Preface

Wilf Stevenson, Director of the Smith Institute

The Smith Institute is an independent think tank set up to undertake research and education in issues that flow from the changing relationship between social values and economic imperatives. In recent years we have taken an active interest in the role of social housing in a progressive society. We have published several monographs on developments in the sector and facilitated debates on what the future might hold. It has been striking that while these have been successful events, the discussions have all too often been frustrated by a lack of detailed evidence.

This study changes that, and provides for the first time a unique longitudinal analysis of the relationship between housing and people's life chances. At the seminar we held in October 2007 to discuss the study's findings, it was generally agreed that the work was not only authoritative and extremely timely but also significant in that it provided a unique insight into the complexities and interconnections of social housing's relationship to how we live and where we live. By reviewing datasets of UK birth cohorts over half a century, the study casts new light on the links between social housing provision, tenants' lives and social policy. In particular it highlights the intergenerational aspects which shape the relationships between housing, place, family, community and public policy.

The study is of course open to interpretation and makes no claims about providing easy answers to the problems facing the social housing sector. However, the research does show how

approaches and attitudes to social housing have changed and how this has affected people's life chances in terms of health, employment, education, social mobility and welfare dependency. It raises important issues concerning the value of social housing and what might need to be considered in order to tackle deep-rooted problems of multiple disadvantage, poverty and worklessness.

In tracking the relationship between housing and people's circumstances and other life outcomes, the study shows that the link between social housing and deprivation is not inevitable. Social housing was until the mid 1960s the tenure of choice for the many. However, the data shows how socioeconomic and cultural factors have reshaped the housing market and demonstrates how social housing policy has been disconnected from our efforts elsewhere to improve people's life chances. The depressing conclusion is that social housing has become an indicator of risk for adult life chances, above and beyond what might be expected. The situation can be reversed, but this will demand greater recognition that the way social housing has been provided has not supported the very people it was meant to help.

The Smith Institute thanks Leon Feinstein and his colleagues at the Institute of Education, the London School of Economics & Political Science and University College London, and gratefully acknowledges the support of the Housing Corporation towards this publication.

Foreword

Steve Douglas, Chief Executive of the Housing Corporation

The Housing Corporation believes that access to good-quality affordable housing makes a real difference to people's lives. As the national affordable homes agency, we are committed to promoting innovation in the delivery of affordable housing and supporting communities to thrive. To underpin this, we support analysis and research to enable continuous improvement in what we do and contribute robust evidence to the development of policy.

Ensuring that our approach to the delivery of affordable homes and to housing policy more widely is informed by the best evidence is particularly important as we move towards setting up the new investor – the Homes & Communities Agency – and the

new regulator, Oftenant. We are delighted to be supporting, along with the Smith Institute, this remarkable piece of research. It provides unique insights into the impact of housing on people's lives and provides a wake-up call to all of us who see affordable housing as more than just the housing of last resort.

As the government pursues an increasingly ambitious vision for housing, it is important that we learn the lessons of the past. Social housing needs to be a force for social justice and provide a platform for better life chances. Going forward, it is essential that we truly realise the benefits of providing good-quality affordable homes in mixed communities, which support both the needs and aspirations of our growing and diverse population.

Introduction

Jim Bennett, Head of Policy at the Housing Corporation

This research study looks at the life chances of people living in social housing from the Second World War up to the current day. It therefore provides a unique overview of the extent to which, since the inception of the welfare state, housing policy has delivered on its objectives and contributed to those of wider social policy.

Social housing, provided by local authorities and housing associations, enables the government to meet its aim that everyone should have the opportunity to access a good-quality and affordable home, including those who are unable to do so in the market sector. However, politicians and policy makers are, rightly, now looking at the extent to which social housing contributes to wider policy objectives. A progressive vision for social housing in the 21st century is one that goes beyond simply housing provided at sub-market costs, but as a means for promoting social justice, personal responsibility and independence, access to opportunities and social mobility.

The 2007 review of the future roles of social housing conducted by Professor John Hills concluded that, while the fundamental rationale for the state to support social housing remains as strong as ever, in important areas social housing is not delivering the kind of benefits we should expect of it. The review concluded that while social housing is popular with many tenants, satisfaction with their homes could be higher. It also noted that as the sector has shrunk, it has become increasingly concentrated in deprived areas and that the levels of worklessness amongst tenants of social housing are higher than they should be.

Hills' recommendations focused on the extent to which management of the existing housing should become more tenant-centred (a sentiment echoed in Professor Martin Cave's review of social housing regulation), on more being done to support tenants' livelihoods and tackle worklessness, and on support for steps to promote more mixed communities. The Hills report was well received in the public policy and housing sectors, and the government has already announced initiatives that reflect some of its recommendations. The conclusions of this research support much of Hills' analysis and add further momentum to the process of reform that has flowed from his review.

The cohort studies provide an extremely powerful resource for social research. The ability to track the position of individuals, across a very wide range of social and economic indicators, from birth through different stages of their life course provides a far greater insight than is possible with snapshot surveys. The cohort studies are being used increasingly in recent years to answer important public policy research questions. This is the first time that longitudinal research of this scale has looked specifically at the relationship between housing and life chances, and the fact that it uses data from four cohort studies makes it particularly significant.

The analysis of the cohort studies that follows shows that there is nothing inherent about social housing provision to suggest that it contributes to worse life chances for tenants. However, it does show that since the 1970s living in social housing has become increasingly associated with poorer outcomes across a very wide range of measures of deprivation and social exclusion. It is important to stress that while the analysis reported here has controlled for a very wide range of variables to eliminate many possible selection effects, the existence of an association between living in social housing and these poor outcomes does not mean that it is social housing that is causing these outcomes.

There are a number of likely reasons for the fact that living in the social housing sector has become increasingly associated with poorer life chances. The first is that over the period since the Second World War the social housing sector has increasingly become the housing tenure of poor households. The changing socioeconomic and tenure profiles of the cohorts provide a very clear picture of the stark tenure polarisation that has occurred. With the increase in owner-occupation that has occurred since the 1940s being concentrated amongst those in higher socioeconomic groups, social housing has almost exclusively become the preserve of the poor. However, the association between social housing and poorer life chances cannot be wholly explained by the changing characteristics of tenants. A significant association remains even after controlling for a very wide range of individual and family background characteristics.

A second possible reason is that previous approaches to the delivery of social housing, for example the construction of large mono-tenure estates, may have inadvertently, in conjunction with the trends noted above, created conditions likely to foster multiple disadvantage.

Thirdly, the research begins to explore the extent to which where people live, as well as their tenure, impacts on life chances. The results indicate that place or area factors may account for a significant proportion of the association between social housing and poorer life chances. The process of polarisation noted above has a significant spatial dimension. As well as poorer households being increasingly concentrated in social housing, social housing has become more concentrated in deprived areas.

Finally, while this study has controlled for a wide range of factors, it is possible that wider structural changes in society and the pathways that impact on life chances could explain some of the patterns identified by this research.

Unpicking these issues will require further research. We are pleased that, as this study reports, we are already embarking on follow-up research. This will address key questions that this study raises, concerning what it is about housing and where it is

located that matters for people's life chances, whether there are particular groups for whom tenure makes a difference to outcomes, and on which particular outcomes tenure matter. This further research should provide important lessons about how we should approach policy for social housing going forward.

In spite of the caveats about causation and the need for further research, the findings of this study are very challenging. They demand the attention of all those with an interest in translating public investment in social housing and the efforts of housing providers into positive impacts on people's life chances. As the

government has set out very ambitious targets for house building, it is essential that we avoid making the mistakes of the past. The targets for new housing include a significant proportion of social housing, to address the unprecedented need for affordable housing, but also to tackle some of the polarisation noted above through delivering more homes in mixed communities. The need for policy makers to have regard to the emerging lessons from this research and the wider debate about integrating and developing holistic approaches to housing with wider social policy is manifest.

Research report and analysis: the public value of social housing – a longitudinal analysis of the relationship between housing and life chances

Executive summary

- This briefing paper reports findings from an original study of social housing from the end of the Second World War to 2003. This wide historical panorama is vital in the study of social housing because so many of the underlying processes and impacts run across generations.
- It is well known that there are currently powerful correlations between social housing tenancy and many aspects of disadvantage. It is also well known that these relationships have existed for some time, at least since the 1970s.
- We investigate the nature of these relationships in more detail, using unique sources of data: four UK birth cohort studies, which provide very rich data from people living in different periods, and which track them across their lifetimes. Our research to date has found two major new results.
- Our first new finding is that the negative correlations now commonly associated with social housing are not inevitable or inherent to provision of housing by the public sector. For those born in 1946, now aged 62, growing up in social housing was not associated with disadvantage. No negative outcomes are evident for men. For women, the first evidence of negative outcomes is at age 53. For those born in 1958, there are negative outcomes for women but not for men, and for those born in 1970, negative outcomes are evident for men and women. These effects persist after controlling for many other socioeconomic and developmental factors.
- This suggests that as society has changed during the post-war period, changes in the availability and nature of social housing, who has got into it, how it has been managed, and how well it has responded to increasing levels of need, have altered the effects that it has had on the people living in it. Over this period, we show how owner-occupation has grown rapidly, while social housing has changed from being a growing sector with new, relatively high-quality housing and little stigma, to a shrinking, ageing sector with a poor reputation. In this process, it has not managed to successfully combat the disadvantage experienced by its tenants and may have added to it.

This first result also suggests that the experience and effect of social housing on the 2000 cohort and other current residents may be different again from that for past cohorts. Unfortunately, the trend appears to be towards stronger correlations between the tenure and disadvantage over time.

- Our second main finding shows that, for those born in 1958 and after, there are links between tenure and life chances that go beyond correlations between social housing in childhood and later disadvantage. Social housing in early adulthood is associated with disadvantage later in adulthood. This is a

substantial development of existing cross-sectional data, looking at people of all ages, which shows an association between social housing and disadvantage beginning in the 1970s. It suggests that social housing may play a role in the persistence of disadvantage – or at least does not manage to overcome its powerful effects.

- Again, these results do not prove that social housing tenancy is causing the negative outcomes. They do, however, again suggest that social housing has not yet been able to go beyond meeting basic housing need to act to halt or reverse persistent disadvantage. These results also begin to strip away possible alternative explanations for what might be going on. There are messages here not just for housing policy but, as more social housing is built, about the need for better linkages between housing and other social policies.
- Further exploration of the data is needed to understand more about any effects social housing tenure may have on its residents, how these effects might be created, when and on whom the effects might be strongest, how this compares with other tenures, and what the implications are for the housing system and housing policy.

Methods

The data used for this study are the UK birth cohort studies, which are large-sample, nationally representative repeat surveys of people born in 1946, 1958, 1970 and 2000.

For the three earlier cohorts we compare adult outcomes for those in social housing at various stages of life, relative to those in the private rented sector and in owner-occupation. These are broad groups, with important differences within groups as well as between them.

We consider outcomes in terms of a very broad set of adult life circumstances, experiences and difficulties. To simplify the material, we present findings in the text based on analysis of a single indicator: multiple deprivation, defined as experiencing more than one of the following adult outcomes:

- workless household;
- workless household with children;
- financial problems;
- permanently sick/disabled;
- depression;
- smoker;
- single parent.

This slants the analysis towards a focus on child poverty, because with this indicator the outcome of “workless household with children” counts double. Any cohort member who in adulthood is in a workless household with children present is necessarily

classified by this indicator as experiencing multiple deprivation. However, this is not a measure of child poverty, as many children experiencing poverty will not be picked up by this indicator.

The data include a wide range of other measures at earlier ages which enable us to control statistically for many of the individual factors that influence housing tenure. In this way, we can go a long way to achieving like-with-like comparisons and be relatively confident that the average differences in outcomes between those in social housing and others reflect the impact of factors related to housing rather than to the selection into housing.

However, the complexity of these processes is such that conclusions about causality should be drawn with considerable care, even when so many control variables are introduced. It is important to recognise the complexity of the many ways in which housing may impact on life chances and how these may interact with personal factors.

Key findings

1. Trends

During the period 1948–65 social housing was growing, and even advantaged groups made use of it. Between 1965 and 2003 there was then a significant divergence, with substantial declines in social housing for most of the population with children, but not for the 20% least advantaged in terms of education and occupation, for whom the proportion in social housing was constant.

Throughout the period there was growth in owner-occupation. However, between 1975 and 2003 the proportion of the most disadvantaged 40% owning their own homes fell, while that amongst the remaining 60% rose. For middle-quintile families, the proportion of owners grew from 34% in 1965 to 64% by 2003. At the same time the growth was small for the second-most disadvantaged quintile and negative for the most disadvantaged quintile.

Thus, despite right-to-buy legislation, there was a stark polarisation in access to the wealth generation that home ownership offered over this period. Moreover, even within the bottom 40% a divergence can be observed: the proportion of owner-occupiers in the bottom 20% is 20%; in the next quintile up it is 39%.

There is now a very strong relationship between residence in social housing and multiple forms of disadvantage and deprivation. For the 1970 cohort at age 30 (2000) we find that those in social housing at aged 30 had odds of having experienced a lot of time "not in employment, education or training" around 11 times higher than those for the rest of the cohort. They had odds ratios over nine times higher of being in workless households, being without degree-level qualifications,

and being single parents. They had odds over two times higher of depression, mental health problems and low self-efficacy and of being dissatisfied with life. This is not in itself evidence of a causal influence of social housing. Indeed it is to be expected in a system in which social housing is allocated primarily on the basis of need. It does indicate the need for adequate support and services for social housing tenants and the need for joined-up policy interventions.

2. The relationship between being in social housing in childhood and adult outcomes

We look at the risk of multiple deprivation in adulthood for those who experienced social housing in childhood, compared with those who were in the private rented sector or in owner-occupation, taking account of a very wide range of prior features of development and circumstance.

- For the 1946 cohort, social housing in childhood was not a significant risk factor for adult deprivation or worklessness, except for females and then only for very recent (age 53) outcomes, (most likely explained by the experience of housing since residualisation rather than because of the experience in childhood).
- For the 1958 cohort there are important gender differences. For males, once the observed selection factors are taken account of, there is no increase in the likelihood of adult multiple deprivation for experience of social housing in childhood. For females there is an increase in likelihood of adult deprivation at ages 33 and 42.
- For the 1970 cohort we find negative outcomes for both males and females in social housing in childhood, even when controlling for other factors.

Thus the association of social housing in childhood and adult difficulties is a relatively recent phenomenon and not inherent to socially provided housing. However, as social housing has become increasingly the option for people with least choice, the association has become very strong indeed and hard to explain away by other aspects of disadvantage, raising serious questions about the failure of recent and current provision to offset the risks faced by those housed by the public and voluntary sectors.

More detailed analysis of this difference between genders is important. It may be explained by long-term consequences of early parenthood, which may have more substantial long-term implications for females than for males.

3. The transition to social housing in adulthood

We find a considerable degree of stability of social housing tenure. For example, males in the 1958 cohort in social housing at age 33 (1991) have odds of being in social housing at age 42 (2000) that are 29 times higher than those not in social housing at age 33.

Within this overall pattern of stability, there is a key transitional moment during the transition from childhood to adulthood. For the transition between age 16 and 23 the odds ratio declines to 6.5, still very large but much smaller than for other intervals. This may indicate a particularly important moment for policy support and action.

4. The relationship between being in social housing in adulthood and later adult outcomes

We find strong associations of social housing in early or mid-adulthood and negative outcomes later on in adulthood, even taking account of a great number of background circumstances, elements of personal development and early adulthood life chances.

For the 1946 cohort the risk of later multiple deprivation for those in social housing at age 36, taking account of some age 36 circumstances and many earlier factors, is on the whole not greater than for those in the private rented sector (except for women at age 43) and is often lower.

This is not so for the 1958 cohort or the 1970 cohort, for whom the adult risks of social housing for later multiple deprivation are substantial and worse than for those in the private rented sector. For example, females from the 1970 cohort who were in social housing at age 26 (1996) had odds six times higher of multiple deprivation at age 34 (2004) than owner-occupiers, even with a substantial array of prior control measures including elements of deprivation and difficulty at age 26.

The risks of social housing are in fact even more substantial if the sample is limited to those from less advantaged childhood backgrounds, suggesting that the apparent worse outcomes are not because those in social housing are being compared with more advantaged private renters or owner-occupiers.

5. Area effects

We find that area may be an element of the explanation of worse outcomes in adulthood for those in social housing in childhood.

When area is taken into account, the remaining negative association of social housing and life chances falls. However, we do not find area to have such an effect for the impact of social housing experienced in adulthood. Much more work is required to offer more robust and detailed analysis of this issue.

Conclusions

Some of the outcomes for those in social housing are hard to explain away as the result of selection factors. They may be due to the life experiences of those in social housing, including high concentrations of enduring and persistent poverty, high demands on the most active for social care for elders, children and the ill and disabled, problems of debt, anxiety, depression and broader mental health problems, social and economic disengagement and disenfranchisement, weak labour market attachment, stigma and discrimination, low levels of occupational stability, poverty trap issues, poor schooling, and changing family structures and relationship breakdown.

By no means are these characteristics true of everyone in social housing, nor, as we show for the 1946 cohort, is it inevitable that they be true of so many people living with a public-sector agency as landlord. However, the mechanisms and partnerships through which the public sector allocates its housing – and land for house building – must be seen in the wider context of general trends in housing, as outcomes will depend on both of these factors.

The report emphasises the importance of better linkage of housing policy and other elements of social and public policy including education, health, work and welfare. There are good grounds for an emphasis on multi-agency working, community ownership and neighbourhood-level interventions. However, there are also questions about how far the state should support owner occupation as compared with other tenures. In the final section of the report we briefly review other possibilities and discuss some difficulties in relation to the important challenge of developing mixed communities.

Section 1

Setting the scene

Setting the scene

Housing is a major element of the agenda of the UK parliamentary programme, with legislation and funding to help provide 3 million new homes by 2020. Social housing is at the heart of these proposals. The housing green paper (DCLG, 2007) signals the government's commitment to the provision of social housing, with at least 45,000 new affordable homes a year to be built by 2010-11 (significantly above the previous annual rate) and a goal to reach 50,000 a year between 2011-14. This is surely good news as it indicates an intention to address this key driver of UK social and economic relations and hence of economic and wider well-being.

However, many questions about the role of social housing and its allocation and regulation are uncertain and have been opened to debate. Two major reviews of social housing, John Hills' *Ends & Means: The Future Roles of Social Housing in England* and *Every Tenant Matters: A Review of Social Housing Regulation* by Martin Cave (Hills, 2007; Cave, 2007) have been published by the government in the last 12 months, raising questions about whom social housing should be for, how it can be integrated with other housing policies that promote home ownership and mixed communities, and how it can facilitate other outcomes such as employment, good health and education.

This paper provides longitudinal evidence of the association between social housing and life chances and evidence for how this relationship has altered as housing policy has changed over the last 60 years. We present original analysis from the UK birth cohort studies, a unique set of resources for investigating social policy issues, including a wide range of data on the lives of individuals as they move through childhood into adulthood and experience different forms of housing tenure at different periods of post-war history. The cohorts span children born in 1946 to those born at the turn of the millennium. Using the UK birth cohort datasets, we investigate the use and effect of social housing for different types of people, at different stages of the life course, in different areas, over more than half a century from 1948 to 2004, and highlight implications for the debate on the use and public value of social housing in the present and future.

We are extremely grateful to the members of the UK cohort studies for having taken part in these remarkable studies over so many years, and to the many academics and administrative staff who have done such a remarkable job over so many years. We hope that both groups feel that this paper is a fair and worthwhile use of the resulting data. All errors and omissions are our own.

Section 2

The relationship between social housing and disadvantage

The relationship between social housing and disadvantage

The relationship between social housing and disadvantage is well known. The sector disproportionately houses the least advantaged households. According to Hills (2007), in 2004 a third of people living in social housing had incomes within the poorest fifth of the income distribution. The proportion of social tenants in employment is 32% and the proportion in full-time employment is 22%. Employment and occupation pathways are less secure for social tenants than for others. Personal wealth and financial assets are also on average extremely low, although that has not always been the case. In the general population in the current era, 7% of young people aged 11-15 in 1994 were unemployed 10 years later, as compared with 19% of those who had grown up in social housing (Sefton, 2007).

Social housing has higher proportions of lone parents than other housing tenures and a high proportion of Bangladeshi and black ethnic minorities, some of the most economically disadvantaged groups. Data from the Families and Children Study in 2005 showed that social tenants are at 6.8% more risk of experiencing five or more family disadvantages, such as worklessness, poor-quality housing, mental health problems and lack of qualifications (Cabinet Office, 2007).

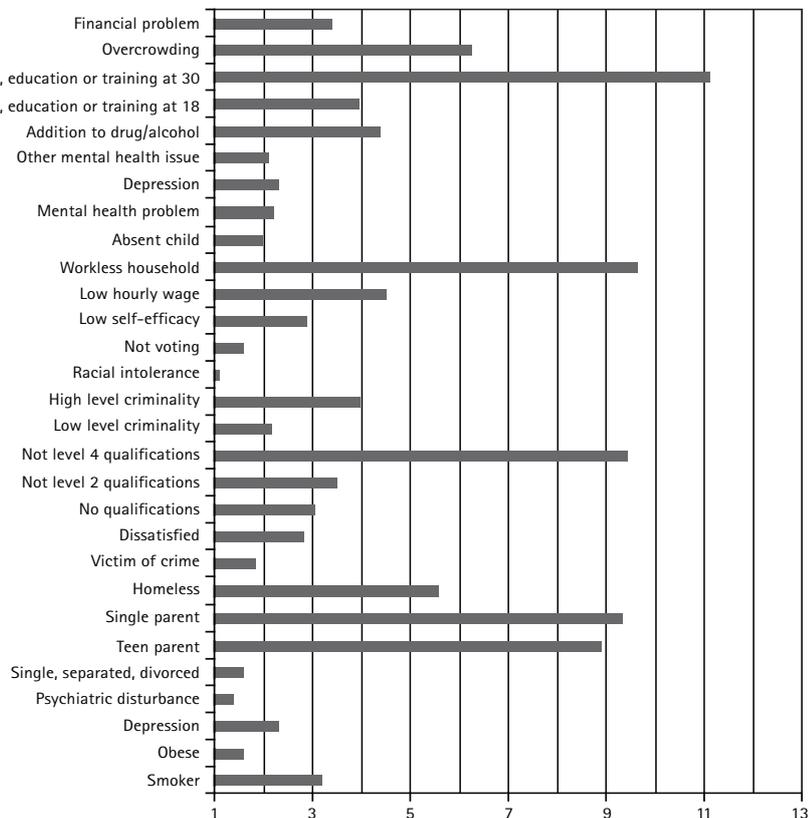

Figure 1, using data from the 1970 British Cohort Study, shows the odds ratio for co-occurrence of elements of multiple disadvantage with social housing tenure in 2000, when these cohort members were aged 30. Multiple disadvantage is broadly defined here to include aspects of economic and educational well-being but also mental and physical health, and elements of citizenship and of family structure.

An odds ratio of two, means for example, that 30-year olds in social housing had odds twice as high of having this characteristic as those of the general population, for example 1/5 instead of 1/10.

The graph does not demonstrate that social housing causes disadvantage. It simply shows the extent to which social housing is related to complex and multidimensional needs, as indeed we might expect in an era in which the allocation of social housing has become increasingly and overwhelmingly needs based. As we highlight below when we turn to the more detailed longitudinal evidence from the cohort studies, there are important intergenerational consequences of housing policy. Any policy framework concerned with child poverty in the UK must take

Figure 1: Social housing tenure in 2000 and multiple disadvantage, 1970 cohort

Odds ratios for co-occurrence of social exclusion outcomes with social housing tenure, age 30

housing into account, and understand its relationship to policies in relation to employment, earnings, work and pensions, education, health and citizenship.

Living in social housing for those in the 1970 cohort in the year 2000 was on average (although not for all) highly associated with all the age 30 measures in figure 1, the single exception being racial intolerance. Of course racial intolerance is not strictly speaking a feature of multiple disadvantage and has been included here in a rather haphazard way. We hope that discussion of the differences between the outcomes will be a subject of a later paper.

The sizes of some of the odds ratios are very large. For example, those in social housing at aged 30 had odds of having experienced a lot of time "not in employment, education or training" (sometimes abbreviated to NEET) around 11 times higher than for the rest of the cohort members. They had odds ratios over nine times higher of being in workless households, being without qualifications at level 4, and being single parents. The graph shows that the needs of individuals in social housing are not only economic but also relate to aspects of their health (over two times higher odds of depression, mental health problems and low self-efficacy), well-being (over two times higher odds of being dissatisfied with life), lifestyles (over four times higher odds of drug and alcohol abuse and over three times higher odds of smoking), crime (four times higher odds of relatively high levels of history of criminality), having had experience of homelessness (over five times higher odds) and poor quality of housing (over six times higher odds of overcrowding).

Note that some of the outcomes shown are measured at earlier periods of life – they are experiences of disadvantage in childhood or early adulthood that most probably led to later social housing tenure, rather than being caused by it. An underlying thread of the paper, however, is how the association of social housing and disadvantage was generated after the Second World War and is not an inherent characteristic of active housing policy on behalf of the public sector.

Other studies have also shown similar associations, and signs that social housing tenure is not just a proxy for other forms of disadvantage. Hobcraft (2002), using the 1958 cohort (the National Child Development Study, NCDS: see below) found that residing in social housing in childhood was associated with a range of unfavourable outcomes at age 33 (in 1991). For both men and women the evidence showed that (compared with those in owner-occupation or private rented tenure) social housing tenure in childhood was linked to poorer outcomes in terms of lower income, lower qualifications, early parenthood and receipt of benefits in adulthood. For men, homelessness in adulthood was linked to residing in local authority housing as a child. There was strong continuity between social housing in childhood and social housing in adulthood, particularly for men.

Sigle-Rushton (2004), analysing the 1970 British Cohort Study (BCS70), found that childhood housing tenure was significantly associated with outcomes such as young parenthood, lack of qualifications, regular smoking and, for men, malaise, characterised by symptoms including depression, anxiety and psychosocial dysfunction, at age 30. Both these studies controlled for many social background characteristics, thus appearing to isolate an effect of social housing over and above these characteristics. At the very least, it appears from these findings that social housing policy has not overall been a sufficient response to individual and household disadvantage.

Such evidence raises concerns about the impact of social housing on life chances and questions about how housing and other welfare policies might work to bring benefits to those in need of social housing as well as those residing in social housing, at a time when more social housing is being built, to ensure that it delivers benefits, rather than disadvantages, to low-income and other households in the future.

In part, as we show below, the high prevalence of multiple disadvantage and poverty for those in social housing is a result of strong macro-social drivers in the history of post-war Britain. In the face of de-industrialisation, the growing demand for skills, area deprivation, the growth of owner-occupation, migration, and changes in lifestyles and family structures, social housing has increasingly had to respond not just to housing need but also to the wider social, economic and structural needs of many of the most disadvantaged in society. Social housing is clearly being efficiently targeted on people who are disadvantaged. However, this is not a role for which it was originally intended. In addition, while it may meet basic housing needs, is it meeting broader social, psychological and economic needs, for example in terms of providing the right environment for childrearing, education or career development? We want to know whether social housing could do more to reduce the disadvantage of those who spend time living in it, whether from birth or as adults. We also want to know whether there is any evidence that something about social housing actually contributes to any of the disadvantages of its residents at all.

These concerns have been noted in a number of government policy documents, not least the Cabinet Office report on improving the life chances of people in deprived areas (Cabinet Office, 2005), and the sustainable communities strategy, with its mixed communities approach (ODPM, 2005a and b). The Cabinet Office Social Exclusion Task Force in its recent document *Reaching Out: Think Family* (2007) gives priority to the most at-risk households, recognising the compounding effect of experiencing multiple disadvantage, including living in social housing. Problems associated with social housing are thus becoming important not just for housing, but also more generally in relation to multiple disadvantage and child welfare. Any policy framework concerned with child poverty and multiple disadvantage in the UK must clearly take housing into account,

over and above the importance of housing for policies in relation to employment, earnings, crime, education, health and citizenship.

To help inform this growing policy debate, we aim to add to the evidence base, building on previous longitudinal analysis, assessing the impacts of social housing over a longer period than any previous research has been able to do, and by taking an

approach that is informed both by an understanding of changes in social housing and by the different functions it has played in the overall housing and welfare system. We work within a strong conceptual model that takes account of the circular and dynamic relationship between housing and other life-course outcomes. In sections 3 and 4 we present these historical and conceptual perspectives, before presenting new findings in section 5, and turning to a policy discussion in section 6.

Section 3

A longitudinal and historical view of social housing

A longitudinal and historical view of social housing

3.1 The British cohort studies

The analysis for this report is based on the use of longitudinal information from four British cohorts born in the post-Second World War era. These are shown in table 1, which also provides information on how long cohort members have been followed up for.

The 1970 British Cohort Study (BCS70) began as the British Births Survey; a sample of all babies born in England, Scotland and Wales in one week in April 1970. Between 1970 and 2004 there have been six attempts to gather information from the whole cohort, with an increasingly broader scope of enquiry encompassing physical and educational development at the age

Table 1: Four UK birth cohort studies

	Early childhood (0-5)	Middle childhood (6-16)	Early adulthood (17-30)	Early middle adulthood (31-45)	Later middle adulthood (45-65)	Later life (66+)
NSHD (1946)					→	
NCDS (1958)					→	
BSC (1970)				→		
MCS (2000/01)	→					

The Medical Research Council's National Survey for Health and Development (NSHD) is the oldest of the British birth cohort studies, prompted by concern over falling birth rates to investigate the cost of childbirth and the quality of associated healthcare. The initial study took as its subjects all 16,500 births that occurred in England, Scotland and Wales during one week of March 1946, and a follow-up survey was designed to examine the health and development of a representative sample (5,362) of this population, which has now been studied 21 times, most recently at age 53 years. The follow-up surveys have followed both policy and scientific concerns (Wadsworth et al, 2006). A small research team has been responsible for these follow-ups, which have been funded by the Medical Research Council since 1962. The MRC Unit for Lifelong Health & Ageing is now responsible for the MRC National Survey of Health and Development. The NSHD is a socially stratified sample of single, legitimate births. Weighting procedures are used to allow for the social stratification.

The National Child Development Study (NCDS) is a continuing, multidisciplinary longitudinal study with an initial focus on perinatal mortality. The study takes as its subjects over 17,000 people born in a single week in England, Scotland and Wales in March 1958. Following the initial birth survey in 1958, there have to date been six attempts to trace all members of the birth cohort in order to monitor their physical, educational, social and economic development. These were carried out by the National Children's Bureau in 1965, 1969, 1974 and 1981; by the Social Statistics Research Unit, City University, in 1991; and by the Centre for Longitudinal Studies, Institute of Education, in 1999/2000 (Power and Elliot, 2006).

of five, physical, educational and social development at the ages of 10 and 16, and then to include economic development and other wider factors at 26, 29 and 34 years of age. These were carried out by the Department of Child Health, University of Bristol, in 1975 and 1980 as the Child Health and Education Study; by the International Centre of Child Studies in 1986 as Youthscan; by the Social Statistics Research Unit, City University, in 1996; and by the Centre for Longitudinal Studies, Institute of Education, in 2000 and 2004/05 (Elliot and Shepherd, 2006).

The youngest of the British cohort studies to date is the Millennium Cohort Study (MCS). The MCS differs from its predecessors by not sampling births from a specific week in 2000, and by including Northern Ireland. The study took as its sample all live births in the UK over 12 months from 1 September 2000 in England and Wales and 1 December 2000 in Scotland and Northern Ireland. The survey for the first sweep took place between June 2001 and January 2003, gathering information from the parents of 18,819 babies born in the UK over a 12-month period and living in selected UK wards at age nine months.¹ The second sweep took place between September 2003 and April 2005, with the children at around three years of age. The MCS is carried out by the Centre for Longitudinal Studies, which is an Economic & Social Research Council resource centre at the Institute of Education.

Looking across these cohorts, we can compare the experiences of people in early childhood at four different historical moments from 1948 (when the NSHD cohort was two years old) to 2003 (when the millennium cohort was aged three), from early

¹ For details of sampling see Bynner and Joshi, 2006.

childhood, through middle childhood, adolescence and various stages of adulthood.

Such an approach is valuable in studying the impacts of social housing. For individuals, housing histories and trajectories may be as influential as current circumstances. How people end up in social housing, why they stay, and for how long, across how many generations, will be important factors determining how it affects them. For this reason, the analysis that follows investigates who is in social housing in childhood, and how this is associated with later outcomes, as well as who moves into social housing in adulthood and subsequent outcomes.

A key point to bear in mind is that cohort members are sampled at birth so, at least in the early sweeps of each cohort, the sample of households in the study is only a sample of households with children. As cohort members move into and through adulthood, the range of households varies more, although not yet including pensioner households. The cohorts to date give an incomplete picture of the impact and value of the social housing system, but, nevertheless, a particularly relevant one since social housing, throughout its history, has mainly been built with the aim of housing families with children, and, moreover, families have featured prominently in policies to decide who gets priority for available social rented homes.

3.2 Social housing 1948–2004

A historical perspective is also important because the amount and quality of the physical stock of housing has changed over time, as have the rules governing its allocation and rent levels. Thus the characteristics of the housing have changed and so has the constituency of people who can access and be affected by it. In addition to absolute features, social housing's characteristics relative to private renting and home ownership are also significant.

Local authorities and voluntary organisations began building homes on a very small scale in the late 19th century. Substantial government-supported council house building did not begin until after the First World War, when the 1919 Housing Act aimed to provide "homes fit for heroes". Development started patchily across the country, but by 1946 all local authorities had taken on a direct housing role. By the time the 1946 cohort was born there were 1 million council homes in the UK (Muthesias and Glendenning, 1994), providing homes for 10% of all households.

The parents of the children making up the 1946 cohort in social housing were likely to have been the first generation in their families to live in council housing, and in the vast majority of cases would have moved in from the private rented sector. The move might have been to their first home as newly married couples, a subsequent move into newer and more spacious accommodation, or, for some of those moving from 1932 onwards, a compulsory move as a result of local authority clearance of the worst slum areas, particularly in the big cities.

From 1932 through to the post-war era, many or even most households would have prized a council letting (Cullingworth, 1966; Burnett, 1980). The vast majority of existing council housing was in the form of terraced and semi-detached three-bedroom houses with gardens, built in "garden city" style at relatively low densities on what were then suburban sites. Many homes built in the earlier part of the period had higher design and space standards and better facilities than some contemporary homes built for sale, and certainly better than ageing, shared high-density Victorian private rented accommodation without modern amenities or gardens. Local authorities in some of the biggest cities had substantial programmes of building four- and five-storey blocks of flats from the 1930s.

Access to council housing was at local authority discretion, in many areas with highly personalised councillor involvement in decisions. With demand exceeding supply, and a high proportion of brand-new and high-standard homes, local authorities tended to prioritise the "deserving" who they thought would be good tenants, many asking to inspect evidence of income, clean rent accounts and homes, and some excluding large families or those with a history of drunkenness or irregular work (Daunton, 1984). In addition, council rents were often higher than in much of the private rented sector, and with patchy rent rebate schemes were unaffordable to the poorest (Daunton, 1984). This meant that:

... council housing went to a limited range of income groups – small clerks and tradesmen, artisans and the better-off semi-skilled workers with average-sized families and safe jobs ... (Burnett, 1980: p233)

However, already from 1932 onwards there was a shift away from "general needs" provision. Central government subsidies carried requirements linking support to "slum" clearance schemes, which provided a route into certain estates, often with lower space standards, and aimed at poorer residents, and some of these carried a social stigma (Burnett, 1980).

By the time the 1958 cohort was born, the housing system had changed substantially. Burnett argued that building in the 1950s in public and private tenures allowed the fastest improvement in housing conditions for all so far in the 20th century (1980). A rush of council house building took place to meet pent-up demand after the hiatus and damage of the Second World War, although still by 1958 the majority of council housing in the system would have been built before the war.

Overall, the size and amenities of post-1945 council homes were better than pre-war ones, some with what were initially novelties such as bathrooms upstairs and fridges, and again exceeding the standards of some new private-sector homes (Burnett, 1980). However, design, location and condition began to vary more. New developments included traditional houses, mixed developments of flats and houses, and experiments with multi-

storey housing and non-traditional design and materials (Muthesias and Glendenning, 1994). On average, council homes were less likely to have gardens and more likely to have rooms above the second storey than were private rented housing. Homes were being built in inner-city areas, suburbs and the first new towns.

By 1953 funding for local authority homes was again tightened and linked to clearance programmes, leading to somewhat reduced space standards and in many cases pressure to rebuild at high densities on tight urban sites. Some of the earliest council homes were by now 30 or more years old and beginning to require refurbishment and updating, which was not a priority for national and local policy. Again, some estates connected with slum clearance carried a social stigma. To summarise, the stock was diversifying, and the experiences of the 1958 cohort would have varied, perhaps depending on whether they were born in social housing or, more likely, moved into the sector from private renting as social housing expanded and slum rental areas were replaced.

Since 1949 council housing was no longer to be aimed at the "working classes" and was to be allocated according to "need". In practice, though, local authorities continued to have freedom over allocation policies and continued to use it to select the applicants, using criteria such as overcrowding, lack of amenities, local residence, TB or war service (Cullingworth, 1966). Existing tenants tended to get priority for moves to new and more attractive homes and areas, except in the case of slum clearance schemes. As local stocks grew and diversified, there were often attempts to match the perceived "quality" of tenants to that of homes. Sixty-eight percent of heads of households were foremen, skilled and other manual workers, compared with 41% of owners (Cullingworth, 1966). In the early 1960s, council tenants had the fewest rooms per person, the most overcrowded of tenures. This reflected councils' prioritisation of families with children (Burnett, 1980), with twice as many children per household as homeowners (Cullingworth, 1966). By this point council tenants were slightly less satisfied on average with their homes than were owners, but it is not clear what drove this response (Cullingworth, 1966).

By the 1970s, the housing system had been transformed. Four million council homes had been built since the 1946 cohort were born, making up more than half of all homes built since the war (Muthesias and Glendenning, 1994). Council housing was approaching its peak of size and diversity. The 1970 cohort would have been the first to contain a substantial number of second- and third-generation council tenants, as parents of children born in 1970 were themselves born in the 1930s or 1940s when council housing was a major tenure. Their experiences in terms of housing conditions, neighbourhood and social circumstances would have varied substantially. However, two-thirds of the post-war homes were, like most of the inter-war ones, houses with gardens, mostly in suburban and new town sites; another fifth were low-rise flats, mostly in inner-city areas (Muthesias and Glendenning,

1994). Multi-storey blocks made up less than 10% of the new homes, and new low-rise high-density schemes were tried.

The gaps between those in different tenures on overcrowding had narrowed significantly (Burnett, 1980), but new quality problems were emerging. Most local authorities had substantial pre-war stocks, now up to 50 years old and clearly below the standard of recent building and much of the private rented sector. They were contemplating reinvestment. At the same time, home ownership was growing, and the 1970s was the first period in which substantial numbers of skilled manual workers – the core of council tenants up until this point – began to have increasing possibility of purchase. Nevertheless, council housing continued to serve as a move-up for those arriving from the worst of the private rented sector, with newer homes easily outstripping standards at least in the worst part of the now-shrinking private rented sector. High demand continued in most areas. There were increasing concerns about the exclusion of some groups, among them some with the greatest needs. Rather than just providing advice, for the first time central government regulated access through the Homeless Persons Act 1977, which gave local authorities a duty to house vulnerable households – particularly families – facing immediate lack of housing.

By 1980, when the 1970 cohort were in mid-childhood, there were over 5 million social rented homes, housing nearly a third of all households in the UK. Writing at that time, Burnett argued that "the most striking improvement achieved in the last century and a half was in the accommodation of the working classes", and that while Victorian regulation had been important, "the transformation of the [merely] sanitary house into a larger, lighter, better-equipped and more comfortable home was principally the result of the involvement of the State" (1980: p307).

However, this period was a turning point. From the late 1970s, while social housing continued to provide mainly larger homes and houses with gardens and to house families, the social housing stock contracted, worsened in condition and became more spatially concentrated. Skilled and semi-skilled manual workers who made up the core of tenants since the 1920s have both reduced in number and changed tenure – by 1991 more than half of this group were owners (Hogarth and Elias, 1991). Social housing has increasingly specialised in housing those without employment and with social problems who in past times would have found accommodation in the private rented sector.

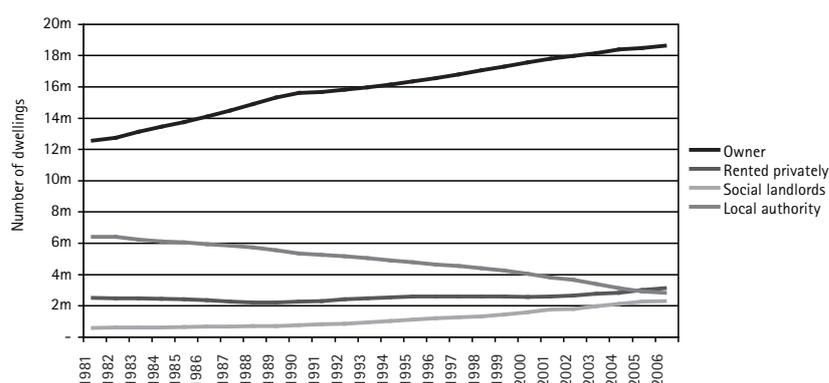

The 1980 Housing Act gave social housing tenants the right to buy their accommodation at a substantially reduced cost. This led to many better-quality council properties being purchased by sitting tenants, leaving the poorer-quality stock in the social rented sector. Between 1981 and 2004, 2.2 million council homes were sold to tenants: one third of all council stock. In the late 1980s, the finance of social housing was reformed, restricting the building of new council homes. During this period house building

slowed down substantially; for example, while 43,000 social homes were built in 1995 this had halved to 21,000 by 2003. Housing associations, seen by the government as more efficient builders and managers, were recruited by the government in the late 1980s to take on the role as main providers of new social housing, but they are on the whole relatively small organisations with much less access to subsidy than local authorities had sustained in their contract with central government for most of the post-war period. They have not replaced council and housing association homes lost through the right to buy.

Moreover, the years of Conservative government (1979 to 1997) were characterised by large declines in investment in social housing, from £13 billion in the early 1970s to £1.4 billion in 2004, leading to a further decline in stock quality. By 1997 approximately 2 million social homes failed to meet government standards and a £19 million worth backlog of repairs remained unaddressed (HM Treasury, 2005).

The result of these trends can be seen in figure 2, which reports data from the Department for Communities & Local Government on tenure.²

Figure 2: Dwelling stock by tenure, UK, 1981-2006

Source: Department for Communities & Local Government

These changes have affected the operation of access policies and also the characteristics of social housing and the effect it may have on life chances. The right to buy and the reduction in the availability of suitable social accommodation meant that many more advantaged tenants changed tenure from the social rented sector over time to move into home ownership. In particular, the right to buy was taken up by older households, without children under 18, and those employed or retired after employment. They disproportionately bought houses, rather than flats, and homes in more attractive and popular areas, resulting in a concentration of building types and locations that were less popular and less likely to be suited to families. At the same time, homelessness legislation meant that those newly allocated to the sector were more likely to be from highly disadvantaged groups including the elderly, poor families and lone-parent families – a switch that has

been described as from "neat and tidy to tight and needy" (Donnison and Ungerson, 1982).

The effect of these changes occurring in tandem is commonly known as the *residualisation* of the social housing sector, and has been accompanied by increasing tenure stigma. By the 1990s even many young children had already learned to view social housing as second-best (Gurney, 1999). On a small scale, social housing has also taken the place of the private rented sector as the target of some government demolition programmes.

For the members of the cohort studies, these trends would have begun to affect the 1946 cohort in their 30s, and the 1958 cohort in their 20s. The 1970 cohort were adolescents when the sector became formally residualised. Those who remained in social housing in 1986 were in families who had not exercised their right to buy.

Moreover, social housing tenants in this cohort also experienced significant economic change. A critical feature of much of the social housing built in the UK since the First World War was that it was built to house populations who worked in large-scale,

geographically stable manual employment. Much, although not all, social housing, replaced the 19th-century terraces of dockers, shipyard workers, miners and textile workers, or housed people working in the new out-of-town industries that expanded after the Second World War – chemicals, motor and aircraft industries and general manufacturing. Many of those living in social housing as children during the 1970s and 1980s were living in families who experienced long periods of unemployment and family poverty when these industries collapsed under the pressure of global competition. Their experiences contrast with the low-income social housing tenants of the 1960s and early 1970s, whose families enjoyed a period of relative economic stability and growth.

By the time the millennium cohort were born, the sector had been shrinking in size for over 15 years, and residualising for 30 years. Intergenerational unemployment in former industrial areas

² <http://www.communities.gov.uk/documents/housing/xls/table-101>

was well established and social and economic inequality much greater than for the cohort born 30 years previously. Children living in social housing in 2004 will in most cases have been born to families allocated social housing since the 1980s, and thus more likely to be cumulatively disadvantaged.

The impact of these trends can be seen in figure 3, which draws on data from all the cohort studies at each age for which childhood data exist to estimate the proportion of children in social housing over time. The first four data points correspond to the 1946 cohort, for information collected at ages two, seven, 11 and 15. The next three data points correspond to the 1958 cohort at ages seven, 11 and 16. The next three data points correspond to the 1970 cohort at ages five, 10 and 16, and finally the last point corresponds to the millennium cohort at age three.

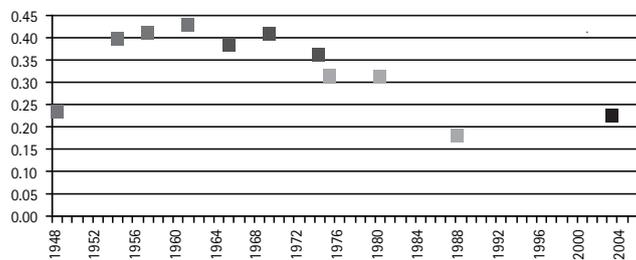

housing was down to 30% at age five, and continued to decline within-cohort to less than 20% at age 16. For the millennium cohort it had remained at around 20% in 2003, age three.

3.3 The rise of owner-occupation

However, looking only at social housing provides only part of the picture. Figure 4 uses the same approach to show the proportion of children in owner-occupied housing in the post-Second World War era.

The proportion of children in owner-occupied housing was a little less than 20% when the members of the 1946 cohort were two years old. Over half of children were in privately rented homes at this time. The proportion in owner-occupation for the cohort increased steadily to over 30% when they were 15 years

Figure 3: Proportion of children in social housing – synthesis across cohorts

The expansion of social housing in the post-war period is clearly demonstrated here. Of the two-year olds in the 1946 cohort, whose tenure was captured in 1948, less than a quarter (24%) were in social housing. The proportion of cohort members living in social housing rose rapidly in the 1950s, to nearly 40% in 1957, reaching 44% in 1961, as their parents took advantage of the growth in social housing supply and the priority given to families.

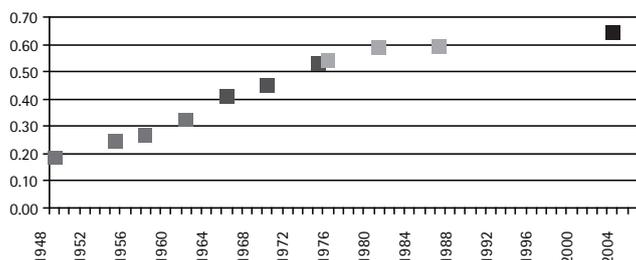

For the 1958 cohort the situation was different. The proportion of cohort members in social housing decreased from about 40% at age seven, rising slightly before falling to 35% at age 16. This suggests that a segment of the parents in the cohort were getting into social housing after young children had already been born – perhaps after time on the waiting list – but then taking advantage of the growing accessibility of home ownership in the 1960s and 1970s. The decline in take-up continued across cohorts. For the 1970 cohort the proportion of cohort members in social

old. It should be noted that this rise in owner-occupation was a within-cohort rise, based on data following the children of the 1946 cohort as they and their families matured.

For the 1958 cohort, the prevalence of owner-occupation was over 40% at age seven (in 1965), indicating a substantial rise between cohorts. The same within-cohort trend is evident for the 1958 cohort, owner-occupation rising to over 50% at age 16 (1974). For the 1970 cohort, the proportion also started from a higher base and continued to rise, from over 53% at age five (1975) to 60% at age 10 (1980), and remained at that level at age 16 (1986). For the children born in 2000, the proportion is slightly higher than for the 1970 cohort in 1986.

The rise in owner-occupation between cohorts is not primarily due to increases in owner-occupation as families mature (the within-cohort effect), but is an overall trend across cohorts. It is

Figure 4: Proportion of children in owner-occupied housing – synthesis across cohorts

also important to note that the trend reaches a plateau in the 1980s, before the introduction of the right-to-buy housing policy. Similar information is provided by Holmans (1987), who showed that the proportion of owner-occupation has grown continuously since 1939. It is one of the major socio-historical trends of the post-war era.

One major implication of these trends is that the roots of residualisation, as a process of social sorting and economic divergence and polarisation, are to be found long before the housing policy changes of the 1980s. It is important to emphasise this macro-social and macro-economic historical trend, as it indicates the power of the context within which housing policy has operated, compared with policy itself.

3.4 Outcomes associated with social housing

The evidence we present in section 5 is by no means the only work to have explored outcomes for social housing tenants in this way. Hobcraft (2002), using the NCDS (1958 cohort), found that residing in social housing in childhood was associated with a range of unfavourable outcomes at age 33. For both men and women an association was found between housing tenure in childhood and outcomes in terms of income, qualifications, early parenthood and receipt of benefits in adulthood. For men, homelessness in adulthood was linked to residing in local authority housing as a child. There was strong continuity between social housing in childhood and social housing in adulthood, particularly for men.

Sigle-Rushton (2004), analysing the 1970 cohort data (BCS70), found that childhood housing tenure was significantly associated with outcomes such as young parenthood, lack of qualifications, regular smoking and, for men, malaise, characterised by symptoms including depression, anxiety and psychosocial dysfunction, at age 30. These studies control for social background characteristics, thus appearing to isolate an effect of social housing over and above these characteristics.

Sefton (2007) offers a more recent analysis of British Household Panel Survey data, highlighting the disparity in employment trajectories between social tenants and others. Between 1994 and 2004, outflows from employment were higher for social tenants than for other tenures. In the general population, 7% of young people aged 11-15 in 1994 were unemployed 10 years later, as compared with 19% of those who had grown up in social housing (Sefton, 2007). Again, it is difficult to separate the effects of social housing from the effects of childhood poverty

and the interaction effects of poverty, tenure and the social effects of de-industrialisation. Many children of manual workers in social housing who were aged 15 in 1994 were young children in the early to mid 1980s, when their families and communities were experiencing job losses and industrial restructuring on a large scale.

Other recent studies have attempted to isolate tenure effects. Galster et al (2006), using US data, links living in owned homes in childhood with an increased likelihood of obtaining graduate qualification and home ownership in adulthood. However, the social housing sector is very small in the US. Homeowners are mainly being compared with people in private rented accommodation rather than with public housing tenants. In a UK study by Bramley and Karley (2005), home ownership was significantly related to improvement in school attainment for primary school pupils.

Burrows (2003) compared poor homeowners with poor renters, including those in social housing, using data from the 1999 Poverty and Social Exclusion Survey of Britain. He found that renters were more likely to be in households where none of the members were working. Poor people living in rented accommodation were also more likely to smoke and experience more social exclusion. For example, poor renters were more often excluded from employment, forced to cut back on their use of basic utilities such as water and electricity, tended to lack on-going social support from family and friends, and were also more likely not to vote. Moreover, poor renters experienced more than one of these aspects of social exclusion more frequently than poor homeowners. However, Burrows also noted a difference in the background of owners and renters. The majority, about 70%, of poor renters were from a manual labour background, whereas homeowners were more likely to have skilled manual or non-manual employment. He also noted that poor homeowners were more likely to report mental ill health and problematic physical accommodation, although they were more likely to be employed. For those on a low income, home owning and renting appear to offer different advantages.

Overall, this evidence appears to suggest that social housing does not seem to create the positive outcomes for people that might be hoped for given the subsidised provision of a stable, maintained home. However, it is hard to demonstrate the effect of social housing per se, over and above the effect of the other social and economic circumstances experienced by social housing tenants at these moments in time.

Section 4

Housing and livelihoods – a conceptual framework

Housing and livelihoods – a conceptual framework

These historical patterns demonstrate very clearly the importance of the processes of selection into social housing in determining outcomes, and the possibility of life-course and intergenerational relationships between outcomes and tenure, as well as between tenure and outcomes. Selection into different housing options depends on the interaction of supply of new lets or purchase opportunities and demands from households, in the case of social housing, mediated through homelessness law and allocations systems. Here we sketch out a model of causation that might help to inform discussion of social housing policy.

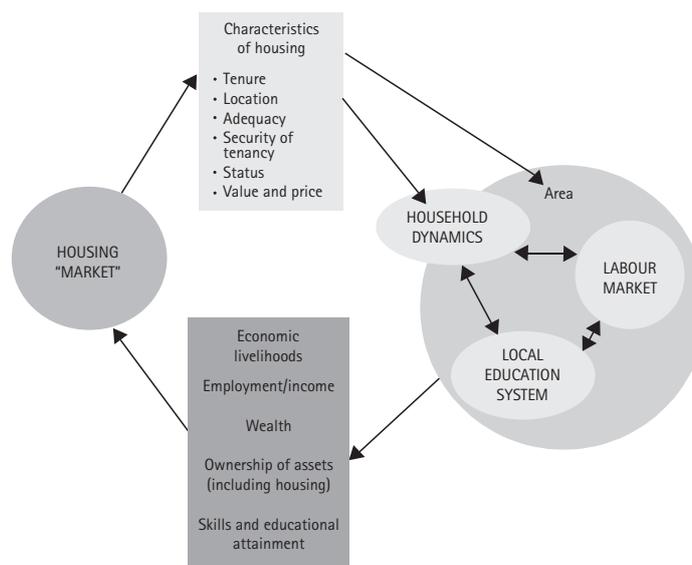

A narrow model of housing and livelihoods is shown in figure 5. This is described as a narrow model because it focuses primarily on the economic dimensions of livelihood, neglecting, with regret, for the moment issues of culture, health and citizenship in order to focus attention on the channels for economic impacts and to introduce some basic principles into the discussion. We hope to look in more detail at wider outcomes in future work.

benefits from social housing, there are also channels for negative consequences. The two may play against each other, interacting also with the selection mechanisms by which people come to be in social housing in the first place.

In the data analysis of later sections we attempt to use the longitudinal data across time to tease apart a little these inter-relationships. Here we set out the conceptual framework, describing what we believe to be key channels of association between the elements of the model.

The first point that should be noted about the model is that it is circular. In line with the discussion above about causality, there are effects of housing on economic livelihoods and effects of livelihoods on housing. The contribution of the model is in highlighting the key elements of housing and livelihood that matter in this context and in showing the mediating channels for these effects. The necessary circularity in

Figure 5: Housing and livelihoods – a narrow model

The key points that we wish to emphasise are:

- i. housing plays a major and insufficiently recognised role in the formation of life chances and livelihoods, within and across generations; but, also,
- ii. there is an important reverse feedback from livelihoods to housing.

Is multiple deprivation more likely for those in social housing because they are in social housing, or are they in social housing because they are experiencing multiple deprivation? As well as

the model is also evident in the fact that, of these characteristics of housing, ownership and value and price could also be considered to be elements of livelihoods, since livelihood encompasses ownership of assets.

Housing demand and supply

Second, the housing market is a key domain of the model. We define the term broadly to encompass both the interaction of market-based demand and supply of housing to determine the allocation of properties for sale and rent in the private sector, and also to encompass the more bureaucratic and needs-based

models of the public and voluntary sectors. These different segments of the market themselves interact on both the demand and supply sides. For example, a decrease in the supply of housing from the private sector will increase demand for social housing. These are standard principles of economics and it should be uncontroversial to expect that an increase in the supply of housing would reduce the price, unless there is a very good reason otherwise. Moreover, crucially, supply decisions have long-term knock-on effects on subsequent generations (Donnison and Ungerson, 1982).

Housing policy has a major impact on livelihoods and on the housing/livelihood relationship through impacts in the housing market:

- on the supply side (through the construction of homes, regulation and planning procedures, the release of public-sector land, changes to the structure for and level of provision of social housing); and
- on the demand side (through regulation, policy and guidance in relation to the provision of social housing, mortgage and tax relief, the structure and payment of housing benefit and other in-work and unemployment benefit transfers).

These are all implicit and explicit policy mechanisms through which the state knowingly and unknowingly mediates and moderates the nature of the impact of personal and household livelihoods on the allocation of housing in society.

Effects of housing characteristics

Third, as the housing box in the model indicates, there are a number of elements of housing that in return are important for livelihoods. Our model highlights:

- location;
- adequacy (quality, facilities and size);
- tenure;
- security;
- status (and broader elements of affective/subjective satisfaction); and
- value and price.

In the data analysis reported in section 5, we focus on tenure as the key variable of interest, differentiating outcomes for those in:

- social housing;
- private rental; and
- owner-occupation.

However, the housing characteristics listed above will vary in important ways between these tenure groups, and this simple threefold set of categories ignores substantial differences within these groups. For example, we do not differentiate in this report between social housing managed by housing associations and that managed by local authorities. Similarly, as we show below,

home ownership exists in a very wide range of areas. Nearly 10% of children in 2001 in owner-occupying families resided in the 10% most deprived areas, and 10% lived in the most advantaged areas. Grouping these very diverse owner-occupiers is a helpful simplification that enables us to focus on some broad average differences but neglects important within-group differences, and we hope not to over-generalise.

The mechanism for tenure effects will involve both the characteristics of housing shown in the housing box in figure 5 and the household and area processes shown to the right of the model and discussed in more detail below. This highlights the complexity of the causal channels and hence both the difficulty of estimation of causal effects and the caution that must be exercised in interpretation.

One important aspect of housing quality may be physical type of housing. One of the substantive differences between those in social housing and other tenures is the high proportion in purpose-built flats in the socially rented sector. In 1998, of those in housing rented from housing associations, 46% were in purpose-built flats, as compared with 39% of those renting from councils, 23% of those renting privately and 6% of owner-occupiers (source: *Social Trends*, 1998). Further research is required to test how this feature of housing and related issues such as density impact on life chances.

There is a considerable body of evidence that the quality of housing can impact on physical and mental health. Research from the USA examining outcomes related to housing quality across a range of tenures found that children living in low-quality housing had greater symptoms of psychological distress, even when accounting for factors such as household income (Evans et al, 2001; Evans et al, 2002). Using the BCS (1970 cohort), Marsh et al (2000) found that housing deprivation experienced in childhood is associated with poor health outcomes in adults not living in deprived housing in adulthood, thus emphasising the importance of past housing tenure on outcomes throughout the life course. In this study, multiple housing deprivation increased the risk of disability or ill health by 25%, and this relationship had a dose-response: increased deprivation over time led to increased probability of ill health.

Blackman and Harvey (2001) reported on a study measuring the mental health of residents before and after the institution of a neighbourhood renewal programme in a deprived area of Newcastle upon Tyne. Following improvements in housing quality and the local environment, residents' perceptions of the area and overall mental health improved. The authors suggest that though improved perception of safety in the neighbourhood was likely to be the main cause for the improvement in mental health, as previous research has shown that improvements made to housing estates have increased the sociability and civility of neighbours, an increase in the experience of social support could also be at least partly responsible for improved mental health

among residents. In support of this is the finding of a significant decrease in smoking. Smoking has often been shown to be a coping mechanism for those in distress without social support.

In another, similar study, a randomised controlled trial in a council housing estate in Plymouth found that improvements in central heating, ventilation, wiring, insulation and roofing were associated with a small but significant increase in the respiratory health of tenants. Even more, during semi-structured interviews that were part of this study, tenants described making greater use of their homes in response to the renovations, improved relationships with their families and an overall increase in their self-esteem (Barton et al, 2007).

Impacts on household dynamics of family life, work and resources

The most obvious characteristic of social housing is that it is subsidised, and certainly we know that this has a significant effect on household budgets. Crucially, the cost of housing will have important impacts on budget constraints for households and so change the nature of the economic relationship to the labour market. As Hills (2007) explains, although the level of rent has no effect on the net gains from working rather than not working, it can make a large difference to the net gain from extra earnings. However, the nature of this relationship will depend on the overall system of tax and benefits. A clear danger for housing policy is that the level of housing benefit tapers very quickly with earnings so as to create a very high marginal tax rate for those in receipt of housing benefit. The provision of secure housing through the social housing system suffers less from this poverty trap problem, if housing is not dependent on worklessness.

Hills (2007) notes that, on average, social renters spend £23 per week on housing compared with £96 for private renters and £132 for those with mortgages. Social rent levels are subsidised and

tenants may claim housing benefit for part of or all the amount. Housing makes up a much lower proportion of the household budget for most social tenants than it does for most people in other tenures. Data from the Family Expenditure Survey from 2003/04 shows that 41% of social tenants spend less than 10% of their disposable income on housing, compared with just 6% of those with a mortgage and 21% of private renters. The purpose of subsidised housing and housing benefit is to ensure that people on low incomes are able to have decent accommodation and to have an adequate disposable income after any housing costs. We are not aware, however, of studies that show the effect of subsidised housing on other areas of household spending or household decisions for people on similar incomes.

Table 2, below, shows other central characteristics of social housing as it is currently provided in the UK, and some of its possible benefits or disbenefits. Social housing is a form of rented housing, which protects its tenants from housing debt and interest rate shocks, and from immobility caused by negative equity or inability to sell. On the other hand, tenants own no housing assets. Their homes are maintained to a publicly acceptable standard, without the need for personal investment, but on the other hand tenants are reliant on landlords for the condition of their homes. These are also features of privately rented homes.

In the UK, social housing is allocated according to need, enabling access to housing and protection from discrimination. However, this may have different effects at different times and in different regions. Social housing is currently offered with secure tenancy, offering stability and protection from home loss in the event of economic shocks, but theoretically inhibiting mobility and (depending on supply) constraining access to the stock for new tenants. Social housing is often clustered geographically, which might have benefits in terms of access to some services and

Table 2: Possible benefits and disbenefits of social housing

Characteristic	Possible benefits	Possible disbenefits
It is rented, not owned	<ul style="list-style-type: none"> • No housing debt • Not affected by interest rate rises • Mobility not affected by negative equity • Property is maintained by landlord 	<ul style="list-style-type: none"> • No housing asset • Reliant on landlord maintenance
It is provided by a non-profit landlord (usually large-scale, usually with clustered provision)	<ul style="list-style-type: none"> • Allocation responsive to need • Security of tenure offers stability and security in event of economic shocks • Protection from poor management or discrimination • Landlord performs wider social role • Clustering enables access to some services, and bonding social networks 	<ul style="list-style-type: none"> • Supply constraints may leave less needy households with unsuitable housing • Long-term tenancies constrain access and mobility • Lack of competitive pressure on good landlord performance • Clustering may limit access to some services, and to bridging social networks and feasible work and training
It is a form of subsidy linked to a home, not to individuals or households	<ul style="list-style-type: none"> • Less disincentive to increase income than with means-tested individual subsidy 	<ul style="list-style-type: none"> • Mobility is constrained by overall supply/demand of social housing

networks, but disbenefits due to the effects of concentrated disadvantage and weak local economies. Finally, housing subsidy is linked to the home, rather than being transportable – an advantage over means-tested individual subsidies, which present real disincentives to work, but possibly a constraint on mobility unless tenants can move freely between homes with similar subsidy.

Perhaps surprisingly, there is relatively little evidence on the effect of these specific mechanisms.

We do know that home ownership is a major contributor to overall wealth (Mitchell et al, 2005). Theoretically, assets provide greater economic stability and are linked to higher attainment, lower marriage dissolution, increased residential stability and civic participation. Length of residence may be driving some of the benefits that are apparently arising from asset accumulation, via increased social capital.

More research is required to understand the incentives of asset accumulation, especially for low income households and the long term effects of asset accumulation.
(ODPM, 2003)

As Burrows (2003) reports, half of the poor are homeowners and there are also costs to home ownership. Anxiety related to increased debt and risk, and costs of maintenance, particularly for older households, may outweigh the benefits of home ownership for some (Askham et al, 1999; ODPM, 2003). Our current analysis does not begin to explore pathways through debt, multiple deprivation and worklessness in different forms of tenure – it is an important issue for future work.

A number of studies have looked at the relationships between tenure and mobility. One obvious drawback of home-based housing subsidies with local allocations and secure tenancies is that tenants may not easily move their home to take up new work. Hills (2007), using evidence from the Survey of English Housing 2006, shows that social tenants move less often than private renters, and less far than other tenures (70% move less than five miles). However, tenants are more likely to move than are owner-occupiers. Sefton (forthcoming) finds that private renters are much more likely to find work by moving and only 3% of moves in the social sector are for job reasons. Various studies show the impact of school choice on the housing market and the moves that parents make to access good schools. Gibbons and Machin (2002) argue that social tenants are constrained in their ability to move to better schools because of the availability of suitable housing.

The idea that it is characteristics of social housing tenure that are constraining mobility is contested. Doogan et al (1996) challenge studies from the 1980s that argue that residence in social housing is a constraint on employment mobility. In contrast to previous analyses, they attribute labour mobility not to individual

factors, but to factors related to the employment market: the transferability of skills and the low level of assistance provided for potential employees to relocate to take up employment. Others argue that some social housing tenants are not unable to relocate for employment, they just elect not to. Those who do move for employment tend to be younger, employed, single, from ethnic minority groups and wealthier (Cho, 2005). A study in London found that only 1% of the social tenants who wanted to or expected to relocate wanted to do so for work-related reasons. Within the sector, they found older and wealthier households were more likely to move longer distances to be closer to family or for work, while family households moved within districts typically for housing reasons. In the USA, studies also suggest a relationship between home ownership and investment in and attachment to an area, which constrains labour mobility (Green and Hendershott, 2001).

Another issue to take into account is that while having the choice or ability to move for employment or education may be important, high mobility in itself may be damaging, for example to social capital or educational progress. High mobility was seen as a problem by many social housing providers in the 1990s.

There are numerous other major differences between the tenures in terms of typical home type, size, quality, location and other attributes. Each of these could act as an influence on who goes into any tenure and on the effects it might have on them. Further research is needed to investigate all the attributes, and any role they may have in explaining the correlation between social housing and disadvantage. We discuss the possible implications of location of homes in different tenures in the next section.

Area and neighbourhood effects

The broader context within which the mechanisms described above may function is represented in the right-hand set of circles in figure 5. We emphasise that there are channels for effects at both the household and the area level and that these interact in important ways with each other and with the characteristics of housing.

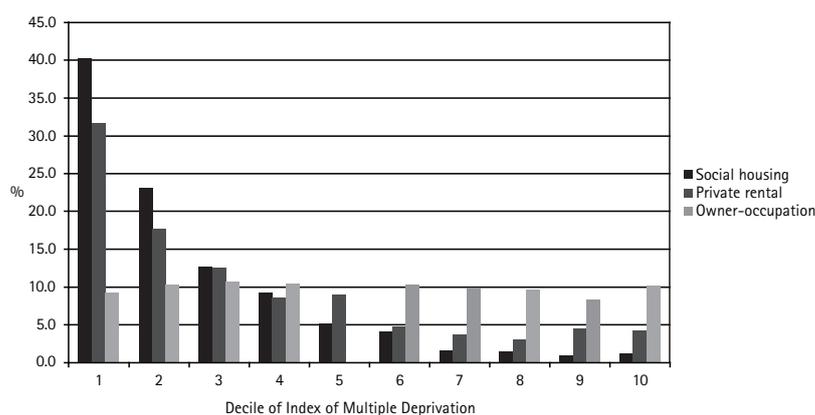

A key mechanism for impacts of housing on livelihoods is through the location of housing and the resulting access or otherwise to labour market opportunities. According to Hills (2007), over 25% of social housing in 2004 in England was located in the 10% most deprived areas, with less than 2% located in the 10% least deprived areas. Similar issues exist in relation to the provision of schooling and other educational and social amenities. Social housing has become concentrated in areas of multiple deprivation, adding to the level of risk faced by social housing tenants.

For today's families with infants this can be seen from figure 6, which reports from the Millennium Cohort Study (MCS) the proportion of nine-month-old children in families in England in

each form of housing tenure living in different levels of area deprivation, by decile of the Index of Multiple Deprivation (IMD). For 2001, 40% of MCS children in social housing in England resided in the 10% most deprived areas, compared with 32% of private renters and 9% of owner-occupiers. For Wales, 28% of MCS children in social housing resided in the 10% most deprived areas, compared with 31% of private renters and 5% of owner-occupiers. For Scotland the equivalent figures are 32% of those in social housing, 9% of private renters and 4% of owner-occupiers.

It is to be hoped that future UK longitudinal data collection will include more multi-level nesting of multiple households within multiple areas, so that we can better model the household-area interaction than is possible here. Crucially, we do not really know which mechanisms cause negative neighbourhood effects and whether changing tenure or income mix would remove these effects. We also do not sufficiently understand how household and area interact.

Figure 6: Proportion of those in each housing tenure, by area deprivation

Source: Millennium Cohort Study

Owner-occupiers are the most diverse group, distributed fairly uniformly across areas, including the most deprived as well as the least deprived. Social housing, however, is particularly concentrated in areas of multiple deprivation.

This is important because of the importance of "neighbourhood effects" and the idea that geographical clustering of low-income households might lead to additional problems, over and above those that individual households might have if they lived in more mixed or affluent areas. We know very little about this across time and in detail, because so many of the longitudinal studies that exist are focused on the individual. The quantitative studies that we do have shed doubt on the importance of neighbourhood effects (Ellen and Turner, 1997; McCulloch, 2001). Much of the evidence is from the USA, where studies have found neighbourhood effects on health, mental health, crime and fear of crime, and, in some cases, education (Berube, 2006). On the other hand, results of residential mobility programmes have shown no substantive impacts on employment or earnings (Orr et al, 2003). In the UK, studies have found neighbourhood effects on labour market outcomes (Buck, 2001) and education (Bramley and Karley, 2005; Gibbons, 2001; McCulloch and Joshi, 2001). But neighbourhood effects, where they are demonstrated, are always smaller than individual or household effects (McCulloch, 2001; Bolster et al, 2007; Joseph et al, forthcoming).

Summary

Overall, the existing literature demonstrates that housing can be linked to a range of outcomes and livelihood factors: health, income, wealth, education, employment, esteem and mental health, social participation and social networks. On the whole, outcomes from social housing appear to be worse than outcomes from owner-occupation. However, the evidence base does not strongly isolate the effect of social housing tenure from the effect of selection into social housing. Nor does it strongly demonstrate the effect of social housing in a dynamic way – over time, at different stages of the life course, and at different historical periods. Nor does it provide an evidence base for policy by demonstrating which aspects of the way in which social housing is currently delivered cause particular outcomes to occur.

This report is not an attempt to fill in all the gaps in the research base. We have two aims. The first is to offer a stronger conceptual model for researching the positive and negative effects of social housing that takes account of the circular and dynamic relationship between housing and other life-course outcomes. The second is to provide new evidence from the analysis of the cohort studies to provide a better basis for understanding the use, effect and value of social housing.

Section 5

New findings

New findings

5.1 The changing relationship between family background and housing in childhood

We have shown above that through the history of post-war Britain there was long-term growth in owner-occupation in housing and first a rise and then a decline in social housing. In this section we consider how these trends played out for different segments of society.

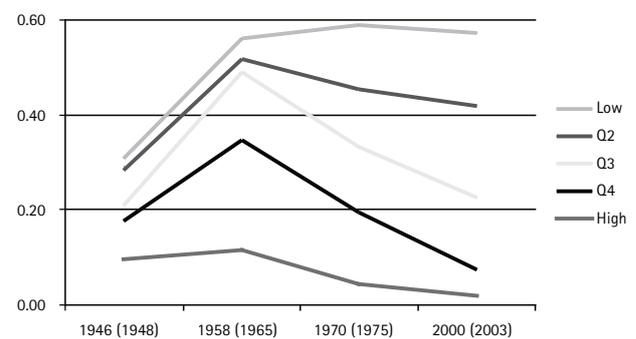

There is a methodological issue here that must be addressed, namely how to categorise families in the different cohort studies into groupings that meaningfully reflect resources in ways that span the period. This is problematic because over time different aspects of family background are measured and, moreover, mean different things. For example, the proportion of parents without qualifications was very high for the 1946 cohort, much lower for the millennium cohort. Thus the two groups are not strictly comparable (technically speaking there are "composition effects"). It is also problematic that we do not have a measure of income for the 1946 cohort.

To address this problem we have created an "index of socially advantageous resources" (or family background indicators) based on three measures that are available across cohorts: the educational qualifications of mothers and fathers and the father's occupation. Using these measures we construct for each cohort an index that ranks parents of cohort members according to their extent of relative advantage in terms of these measures. Education and occupation are closely correlated with income, particularly cross-sectionally, and so this is a meaningful index of advantage even if partial. Sensitivity analysis in the 1958 and 1970 cohort studies, for which we do have measures of income, suggest that the omission of income does not change the kind of findings reported below. Fuller forms of the index would include not only income but also housing asset, and wider forms of human, social and identity capital.

However, for current purposes, this partial form enables us to compare groups in different time periods but who have similar relative positions in their cohort in terms of a vital set of resources to enhance livelihoods. We can then compare, for example, the housing tenures of those in the bottom 20% of the index for the 1946 cohort and those in the bottom 20% of the index for the millennium cohort. Doing so does not suggest that the two groups are similar in terms of their absolute levels of education or occupation. Rather, what is common is their position relative to others in their era in terms of ownership of educational and occupational resources that are vital for livelihoods and economic functioning. This enables us to focus on issues of equality and inequality.

An example of this is shown in figure 7, which reports the proportion in social housing in each quintile of the family background index.

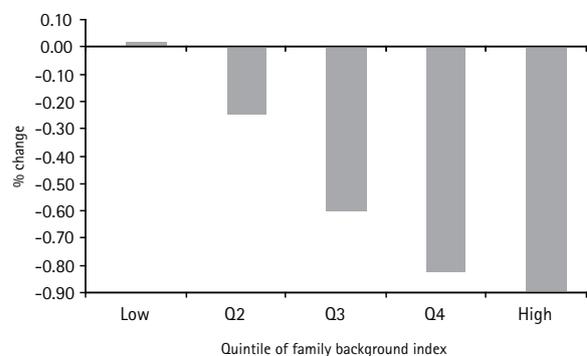

Figure 7: Proportion in social housing by quintile of family background index

It can be seen that across the four cohorts the growth in social housing between 1948 and 1965 was universal at all levels of social advantage but strongest for the bottom 60% of the population and lowest for the most advantaged 20% in terms of occupation and education. During this period social housing was growing, and was sufficiently attractive that the advantaged groups who were most likely to have access to home ownership might nevertheless still make use of it. Between 1965 and 2003 there was then a significant divergence, particularly between the bottom 20%, for whom the proportion in social housing was constant, and the rest of the population, for whom there were substantial declines in social housing.

These changes themselves are graphed in figure 8, which shows how much the proportion in social housing changed in each of the quintiles of the family background index, over the period 1965 to 2003. The general polarisation in housing is evidenced by the gradient of this chart, which shows how the move away from social housing was greater the greater the level of advantage in the household.

Figure 8: Change in the take-up of social housing, 1965-2003, by quintile of family background index

Equivalent changes in uptake of owner-occupied housing are highlighted in figure 9 and its complement figure 10. What is striking here is the divergence between 1975 and 2003 in the

experiences of the bottom 40% of the distribution by family background index and the rest of the population of households with children. In this period, the proportion of the most disadvantaged 40% owning their own homes fell, while that amongst the remaining 60% rose. For those in the middle quintile of the index, the proportion of owners grew from 34% in 1965 to 64% by 2003. At the same time the growth was small for the second-most disadvantaged quintile and negative for the most disadvantaged quintile.

Thus, despite right-to-buy legislation, there was a stark polarisation in access to the wealth generation that home ownership offered over this period. Moreover, even within the bottom 40% a divergence can be observed: the proportion of owner-occupiers in the bottom 20% is 20%; in the next quintile up it is 39%. However, it is important to note that while differences in access to wealth generation increased, it is possible that housing conditions for the most disadvantaged group improved over time, for example by moving from owned but old and slum-standard homes to new council ones with all mod cons.

Figure 9: Proportion of families in owner-occupation by quintile of family background index

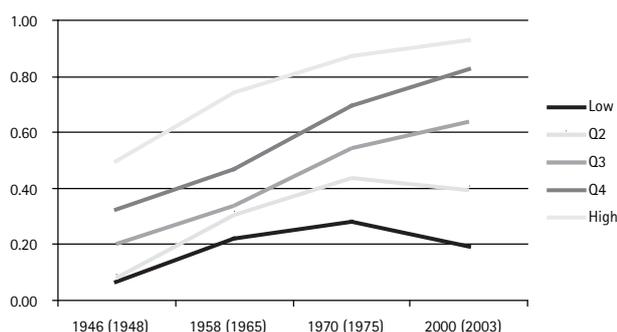

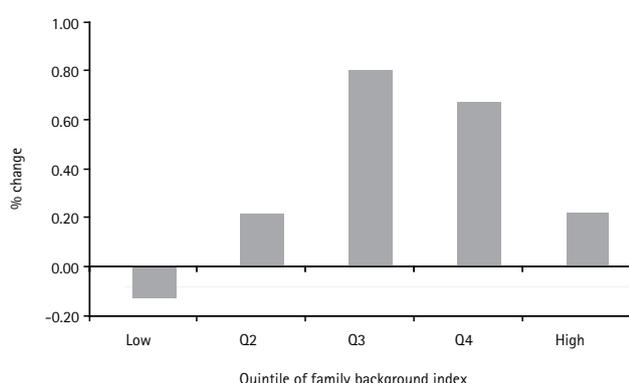

Figure 10: Change in the take-up of owner-occupation, 1965-2003, by quintile of family background index

5.2 Methods for further results

In the remaining parts of section 5 we consider:

i. the outcomes in adulthood of those who experience social housing in childhood;

ii. the transition to social housing in adulthood;
 iii. the impact of social housing in adulthood; and
 iv. the effects of area.

The datasets for the analysis have been described above. We describe briefly the methods for the investigations listed below as we introduce each of the next subsections. However, a few general methodological comments are required.

Firstly, we are interested in the changing relationship of housing tenure to wide-ranging forms of multiple disadvantage, life chances and livelihood over the period since the Second World War. We have undertaken analysis across a wide range of measures of occupational and economic functioning, educational success, mental health and well-being, elements of citizenship, health behaviours and family structure. However, in order to simplify the presentation of findings in the text, we report findings primarily in terms of a single indicator of multiple deprivation we have developed at each age in each cohort. We define multiple deprivation here as the experience of more than one of the following seven elements of deprivation and exclusion:

- workless household;
- workless household with children;
- financial problems;
- permanently sick/disabled;
- depression;
- smoker;
- single parent.

This is not a perfect indicator and any single summary measure reduces information, but sensitivity analysis suggests that the findings according to this single indicator do not vary greatly from those derived using other summary indicators such as the total number of individual negative outcomes. Moreover, the general pattern of findings across cohorts, by gender, age and subgroup, is very similar for this single measure as for the overall set of separate indicators. Presenting findings from the single measure reduces the quantity of statistical material. Summary statistics for these summary indicators are presented in table 3.

Table 3: Summary statistics for binary measures of multiple deprivation

Cohort	Age	Year	Obs	Mean	s.d.	Min	Max
1946	43	1989	7310	0.10	0.29	0	1
1946	53	1999	6048	0.16	0.36	0	1
1958	33	1991	7047	0.15	0.35	0	1
1958	42	2000	11261	0.15	0.36	0	1
1958	46	2004	9191	0.07	0.26	0	1
1970	34	2004	9534	0.10	0.30	0	1

Stepwise analysis, control variables and causality

A second point to note is that we are often interested to see both the raw, bivariate association of housing tenure (social housing, private rental, owner-occupation) and outcomes and the association once statistical controls have been introduced to remove the part of the association that is explained by observed other factors.

One of the great strengths of the UK birth cohort studies is the great variety and depth of measurement. This, together with the fact that assessment starts at birth, means that it is possible to take account of many of the factors that might otherwise explain the correlation of social housing and adult deprivation, so that we can be considerably more confident than would otherwise be the case that observed statistical associations are due to the impact of housing tenure rather than to the factors that lead individuals to be in social housing in the first place. However, the data are not from randomised controlled trials and there are always unobserved elements with which one must be concerned. Considerable caution must therefore be exercised. We return to this issue in the conclusions.

Our intent in this report is epidemiological. We do not seek to prove or disprove causal hypotheses. The aim is to allow the data as much as possible to represent the lives of the individuals in the survey and so aid understanding of what the important pathways and mechanisms might be. However, we work from a model that recognises that there is always heterogeneity (diversity and difference) in individual experience and that the attempt to estimate simple causal models risks too easy over-generalisation.

The coded control variables are classified in the following categories:

- i. family distal factors (socioeconomic and demographic measures);
- ii. family proximal factors (elements of the internal home environment);
- iii. sample member's cognitive development;
- iv. sample member's affective and behavioural development; and
- v. school context (features of peer group and school type).

The list of measures coded in each cohort study is shown in Appendix tables 1.1 - 1.3. Thus, when reporting the association of adult outcomes and childhood tenure with controls introduced (the conditional association), we are seeing the part of the covariation of housing tenure and adult outcome that is not explained by the control variables: family background (including education, occupation, income, family size, lone parenthood, parental aspirations and well-being); child development (cognitive skills throughout childhood and wide-ranging measures of emotional development and self-regulation and behaviour); school type and school intake. These are not causal effects per se but they are strong associations that are often hard

to explain away as unrelated to tenure. However, with such uncertainty about the causal processes that might explain such associations there are firm grounds for caution in interpretation.

Subgroups

We report results not just for the samples overall, but also for particular subgroups of interest, namely by gender, for those in the bottom 40% of the family background index in childhood, and for those in the bottom 40% of the family income distribution in childhood.

5.3 Outcomes in adulthood

In table 4, we report the odds ratios for the summary indicators of multiple deprivation in adulthood for those who experienced social housing in childhood and for those who experienced private rental, as compared with those who experienced neither of these forms of housing in childhood. At this point results are presented only for the 1958 and 1970 cohorts, as we do not yet have sufficient information on private rental for those in the 1946 cohort (although see table 6 for results that do include the 1946 cohort). This is a very broad comparison, as we are comparing the outcomes for those who ever experienced social housing with those who were not in social housing at any observation, regardless of the age or duration of experience. In table 4 no control variables are introduced. Therefore this is purely descriptive.

Table 4: Odds ratios for multiple deprivation in adulthood by housing tenure in childhood (0-16)

Cohort	Age	N	Social housing	Private rental	Diff – p. val
Males					
58	23	3316	1.60***	1.09***	0.013
58	33	2501	2.63***	0.89***	0.000
58	42	4274	2.01***	1.35***	0.005
58	46	3554	2.08***	1.16***	0.019
70	26	2690	2.04***	0.80***	0.000
70	30	3728	2.15***	1.09***	0.000
70	34	3191	2.15***	0.95***	0.000
Females					
58	23	3175	2.21***	1.53***	0.005
58	33	3187	2.34***	1.22***	0.000
58	42	4491	2.36***	1.20***	0.000
58	46	3789	1.64***	1.18***	0.034
70	26	3263	2.89***	1.11***	0.000
70	30	4019	2.44***	1.25***	0.000
70	34	3529	2.71***	1.20***	0.000

Note: ***, ** and * denote statistical significance at 1%, 5% and 10% respectively. The final column reports the statistical significance of the hypothesis test that the coefficient on social housing is not greater than that on private rental. The p-value indicates the likelihood that the hypothesis is falsely rejected. A value of less than 0.01 indicates statistical significance at 1%, ie, less than 1% of a chance that the conclusion that the coefficient on social housing is greater than that on private rental is erroneous.

The first point to note is that across cohorts, ages and genders those in social housing and private rental in childhood had worse outcomes in adulthood than those in owner-occupation in childhood. The difference between those in social housing and

private rental is indicated by the final column, which tests the hypothesis that the odds ratio for those in social housing is higher than for those in private rental. This difference is statistically significant across the period. However, this takes no account for selection: ie, who is in social housing in the different periods.

Table 5 reports the results when control variables are introduced. As noted above, this therefore knocks out the impact of a wide range of social variables and discounts much of the selection effect. The effects seen above for private renting have largely fallen away. Nevertheless, substantial differences remain for social housing relative to owner-occupiers.

Table 5: Odds ratios for multiple deprivation in adulthood by housing tenure, conditional

Cohort	Age	N	Social housing	Private rental	Diff – p. val
Males					
58	23	3316	1.16	0.91	0.104
58	33	2501	1.34	0.70	0.032
58	42	4274	1.11	1.07	0.423
58	46	3554	1.38	1.14	0.278
70	26	2690	1.35	0.57	0.003
70	30	3728	1.47***	0.86	0.001
70	34	3191	1.54***	0.88	0.013
Females					
58	23	3175	1.35**	1.38***	0.458
58	33	3187	1.40***	0.95	0.013
58	42	4491	1.51***	0.92	0.001
58	46	3789	1.18	1.00	0.210
70	26	3263	1.62***	0.96	0.016
70	30	4019	1.61***	0.97	0.000
70	34	3529	1.75***	1.01	0.002

See notes to table 4.

Additionally, the results differ substantially by gender. For males, the odds ratio for multiple deprivation in adulthood for those in social housing in childhood is not substantially or statistically higher than for those in owner-occupation in childhood, or than for those in the private rental sector (except for by age 34 in the 1970 cohort). For females, on the other hand, the difference in outcomes is already apparent for the 1958 cohort. Outcomes are on the whole worse for those in social housing than for either those in owner- occupation or those in private rental.

This broad pattern of findings is also apparent in the unreported analyses across a much wider range of outcomes and by gender and also by subgroup. It holds for those in low-income households in childhood, as for those from families with relatively low levels of education and occupational skill and status.

Table 6 brings the 1946 cohort into the picture, reporting the additional likelihood of the summary outcome for each sweep in childhood at which the sample member was in social housing. No other measures of housing tenure are included here, so the

reported marginal increase indicates the increment to the probability of multiple deprivation for each sweep in childhood at which the sample member was in social housing (taking values 0-3).

Table 6: Effect of increases in exposure to social housing (by number of sweeps in social housing) on chances of multiple disadvantage

70	34	3529	4.48***	2.13***

See notes to table 4. The control variables introduced in the final column are summarised in Appendix tables 1.1 - 1.3. They encompass measures of distal and proximal family background in childhood, cognitive and affective and behavioural development to age 16 and school contexts.

Here we see a similar and striking pattern across cohorts and genders. When control variables are introduced, for males there is no increase in the likelihood of adult multiple deprivation for experience of social housing in childhood, except for the 1970 cohort. For females there is an increase in likelihood of adult deprivation at age 53 in the 1946 cohort, and at ages 33 and 42 for the 1958 cohort as well as for the 1970 cohort.

More detailed analysis of this difference between genders is important. One hypothesis is that it might be explained by long-term consequences of parenthood, which may have been more substantial for females than males.

It is also noteworthy that although there are not long-term risks for males in the 1946 cohort from social housing, there are for females. These risks are not apparent by age 43 but only by age 53. A likely explanation is that this is not an impact of the early childhood experience but of staying in social housing through adulthood during the period of residualisation. Again, further analysis is required.

Overall, a key finding of tables 4-7 is that social housing in childhood is not necessarily a risk factor for adult deprivation but has become so for later cohorts, as the process of movement into owner-occupation has taken place and broad residualisation has left increasingly vulnerable members of society in social housing. The evidence from the 1946 and 1958 cohorts, particularly for males, suggests that this long-term risk is not an inherent feature of living in socially provided housing but is more strongly related to the broader social processes that have deepened the polarisation between those in social housing and others.

Nonetheless, it is striking that even with so many control measures introduced, some of which are themselves possible channels for social housing effects, there are still apparent differences in adult outcomes between those in social housing in childhood and others. For example, males in the 1970 cohort in social housing had odds 86% higher than those in owner-occupation of leaving school without qualifications, even once analysis has controlled statistically for family background, parental aspirations, school peer group and the child's own cognitive and emotional development to age 16. This is hard to explain other than as a consequence of alienation and disengagement from school pathways, which may be a product of interactions with parents, peers, teachers and neighbours but to which the school system does not appear to have responded adequately.

5.4 The transition to social housing in adulthood

Another key finding of this study has been in terms of the considerable stability of social housing tenure. An example of this is shown for the 1958 cohort in table 7, which reports the odds ratios of being in social housing from one sweep to the next.

Table 7: Odds ratios of being in social housing if in social housing in previous sweep, 1958 cohort

Age 1	Age 2	Males	Females	All
	(date)			
7	11 (1969)	71.8	73.6	72.6
11	16 (1974)	50.2	49.7	49.9
16	23 (1981)	6.5	6.4	6.5
23	33 (1991)	50.0	30.2	37.8
33	42 (2000)	28.7	37.3	33.6
42	46 (2004)	204.9	210.9	206.0

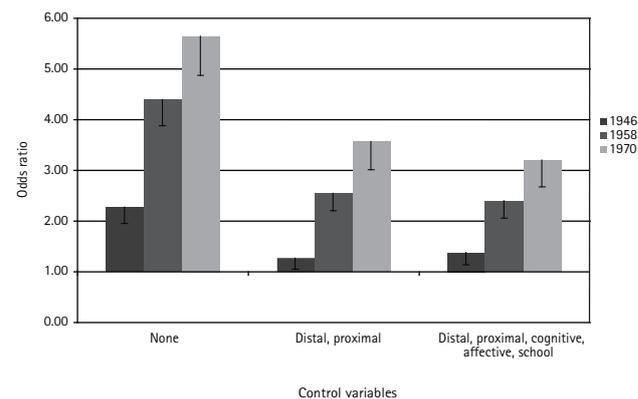

Note: No control variables are included.

These odds do not take account of other factors (bivariate) but are extremely large. Males in social housing at age 33 in this cohort have odds of being in social housing at age 42 that are 29 times higher than those not in social housing at age 33. Within this overall pattern of stability, there is a key transition moment during the transition from childhood to adulthood. For the transition between age 16 and 23 the odds ratio declines to 6.5, still very large but much smaller than for other intervals.

Figure 11 shows how this stability has changed for different cohorts but that it persists in all three cohorts even when control variables are introduced into the analysis.

As control variables are introduced the persistence of social housing over this transition is substantially reduced but remains statistically significant for all three cohorts. It is strongest for the 1970 cohort, much weaker for the 1946 cohort.

Figure 11: Probability of ever being in social housing in adulthood (age 23+) if in social housing at any time in childhood (0-16)

5.5 The sequelae of social housing in adulthood

We now report stepwise regression results estimating the increase in probability of multiple deprivation for those in social housing and, separately, private rented housing relative to those in owner-occupation at earlier stages of adulthood. The time sequencing for the three cohorts is:

- 1946 cohort – tenure at age 36, outcomes at ages 43 and 53;
- 1958 cohort – tenure at age 23, outcomes at ages 33, 42 and 46;
- 1970 cohort – tenure at age 26, outcomes at age 34.

A key element of this analysis is that because we are considering outcomes by housing tenure in adulthood, we can control statistically not only for all the elements of childhood circumstance and development considered in the earlier analyses but also for adult circumstances observed at the same sweep as housing tenure. For example, for the 1958 cohort we can see the consequence of age 23 housing tenure conditional on the following age 23 characteristics: workless household; workless household with children; unskilled or semi-skilled occupation; not employed or self-employed; low hourly wage; literacy or numeracy problem; long-standing illness/disability; permanently sick/disabled; depression; smoking regularly; single parent; child born before cohort member was 20 or 23; no training or apprenticeships since age 16.

Results are presented in table 8 for the summary indicators of multiple deprivation.

It becomes increasingly hard to explain these associations by selection effects, but, because of all the caveats described above about the complexity of the causal pathways and the difficulty of observing and measuring all the many elements of the model in figure 5, we do not call these associations effects but rather "sequelae", which is more descriptive. They may result from effects of tenure type, other housing characteristics, area factors or from selection effects.

Table 8: Odds ratios for multiple deprivation in adulthood by housing tenure earlier in adulthood

Cohort	Age	N	Social housing	Private rental	Diff – p. val
Males					
46	43	3295	3.12***	4.63**	0.143
46	53	2743	0.85	0.49	0.157
58	33	3040	3.83***	2.40***	0.061
58	42	5030	2.10***	1.39**	0.009
58	46	4233	2.13***	1.04	0.012
70	34	4191	12.26***	1.46	0.000
Females					
46	43	3363	1.48**	0.48	0.004
46	53	2734	2.41***	3.57***	0.095
58	33	3854	2.66***	1.77***	0.014
58	42	5488	1.97***	1.47***	0.023
58	46	4658	2.27***	1.41	0.009
70	34	4699	5.95***	1.57**	0.010

See notes to table 4. Reported odds ratios are conditional on distal and proximal family controls plus child affective and cognitive controls, plus early adulthood controls.

The results here are slightly different from those for the long-term risks associated with childhood experience of social housing. The risks for males are as or more substantial than those for females, but again there are important gender differences that require further exploration and analysis.

For the 1946 cohort the risk of later multiple deprivation for those in social housing at age 36 (in 1982), taking account of some age 36 circumstances and many earlier factors, is on the whole similar to those in the private rented sector and often lower (though not for females at age 43). This is not so for the 1958 cohort in 1991, 2000 or 2004 or the 1970 cohort in 2004, for whom the adult risks of social housing for later multiple deprivation are substantial and worse than for those in the private rented sector. The risks of social housing are in fact even more substantial if the sample is limited to those in the bottom 40% of the family background index in childhood, suggesting that the apparent worse outcomes are not because those in social housing are being compared with more advantaged private renters or owner-occupiers.

5.6 The importance of location: special analysis of the age 16 and age 23 sweeps of the 1958 cohort

In a final section of analysis, we take advantage of the fact that, for the age 16 and 23 sweeps of the 1958 cohort, data was matched in by the Centre for Longitudinal Studies to link census area-level data to cohort members. For these two ages in this

single cohort we know about the population of the areas in which sample members resided at both enumeration district (with an average size close to 200 households) and the larger local authority level. This enables us to go some way to test the extent to which area factors explain the strong associations of social housing and deprivation for housing in childhood (table 11) and adulthood (table 12).

Table 9 reports the five census measures used to construct an index of area deprivation at the enumeration district level and the weights given to each item in a factor analysis used to generate a single index of area deprivation.

Table 9: Measures used for derivation of area deprivation indices

Census variable	Weight for age 23 index at ED level
% unemployed + sick, 1971 census	0.30
% in professional + managerial occ, 1971 census	-0.54
% in unskilled manual occ, 1971 census	0.49
% in owner-occupied housing, 1971 census	-0.82
% council tenants, 1971 census	0.80

Note: Indices created at age 16 and 23 and at area level of enumeration district (ED) and local authority (LA).

These measures are combined into four indices of area deprivation as shown in table 10, which also reports the Cronbach's alpha measure of inter-item correlation for each index. These show good reliability.

Table 10: Cronbach's alpha for deprivation factors

Age	Area	Alpha
16	ED	0.73
16	LA	0.87
23	ED	0.78
23	LA	0.88

Note: ED = enumeration district; LA = local authority.

We then introduce the area measures into the analysis of the previous section. Table 11 reports the changing marginal "effects" (dF/dX) of social housing and private rental at age 16 on the measure of multiple deprivation at 33, relative to owner-occupation when the age 16 area measures are introduced, in addition to the full range of childhood controls.

Table 11: Marginal increase in probability of multiple deprivation in adulthood at age 23 by housing tenure at age 16, controlling for full set of childhood covariates

	No area controls	Area controls
Social housing	0.064***	0.045***
Private rental	0.077***	0.070***
Area deprivation at ED level		0.057***
Area deprivation at LA level		0.011

Note: Table 11 reports the marginal increase in the probability of the outcome. Reported estimates are conditional on distal and proximal family controls plus child affective and cognitive controls to age 16.

The results are presented here for the age 23 summary measure but are very similar for later ages. The two key findings are, firstly, that the estimated "effect" on social housing is substantially reduced (by 42%) when the area measures are introduced. In other words, with these measures we cannot knock out all of the remaining association of age 16 tenure with later outcomes but it is substantially reduced, beyond the impact of having introduced child-level controls. Thus, area matters. If we had more detailed information on area in the previous tables we can presume that the negative relationship of social housing in childhood and adult outcomes would have been further reduced. More work needs to be done on this in the cohort studies and elsewhere.

Secondly, it is interesting to note that it is the information about the very local area (enumeration district) rather than the broader area (local authority) that is predictive for subsequent outcomes.

Although we find that the association of adult outcomes with childhood housing tenure is in part mediated by area, we do not find this for the relationship of later adult outcomes with age 23 housing tenure. This is shown in table 12.

Table 12: Marginal increase in probability of multiple deprivation in adulthood at age 33 by housing tenure at age 23, controlling for full set of childhood factors

	No area controls	Area controls
Social housing	0.083***	0.078***
Private rental	0.053***	0.052***
Area deprivation at ED level		0.008*
Area deprivation at LA level		0.006
See notes to table 11.		

There is very modest attenuation on the social housing estimate, which falls from 0.083 to 0.078, a decline of 6%. The enumeration-district area variable itself is statistically significant at 10% but small in magnitude.

In this brief analysis we have only scratched the surface of what might be done in these data to model mobility between ages and tenures at different ages in different cohorts. We postpone such more detailed analysis to future work. However, the analysis has shown that area effects can be substantial, particularly in childhood or adolescence. When area is taken account of, the apparent negative impact of social housing tenure in childhood on life chances is reduced substantially, suggesting that area deprivation may be an important channel for effects.

Section 6

Conclusions and policy discussion

Conclusions and policy discussion

Overview

We find that through the period after the Second World War there was first growth and then decline in social housing supply and demand, alongside rapid considerable growth in owner-occupation and broad residualisation and the increasing concentration of the most vulnerable in social housing. It does not appear that social housing or wider social policy has risen to this challenge.

The findings from the 1946 cohort suggest that there is nothing inherent to housing that is designed, built, financed, owned, and/or managed by the state that makes it damaging or the cause of multiple disadvantage. For those in the 1946 cohort in social housing in childhood, there was not additional risk of multiple deprivation relative to being in the private rented sector once selection factors are accounted for (table 6). For those in the 1946 cohort who were in social housing in adulthood, there was some degree of risk of later deprivation (table 8) but this is on the whole less than the risk of being in the private rented sector. For the 1958 cohort and even more for the 1970 cohort, social housing in childhood or adulthood had become a substantial risk factor.

Given the wider social trends, social housing has become increasingly the source of housing for the worst-off and least able to respond to labour market pressures, technological, educational and cultural change and other drivers of multiple disadvantage.

We see this evidence as supporting the view that housing policy has been too distinct from other elements of government policy on education, health, social services, tax and benefits, and work to respond adequately to the increasingly concentrated and multiple elements of deprivation experienced by social housing tenants. Social housing in these data has become an indicator of risk in the sense that, even with broad and comprehensive control variables, it is still on average a predictor of worse outcomes than tenure in the private rental sector or than owner-occupation. This very strong association with negative outcomes indicates a substantial challenge for housing policy in conjunction with social and economic policy more generally. We believe that the evidence presented in this report and elsewhere shows that the reduction of multiple disadvantage for those in social housing should be a central goal of policy for any government that claims to be concerned with the needs of the worst-off in society.

The building and maintenance of social housing stock without investment in and support for the people who reside in it will not enable the government to meet targets in relation to social exclusion, child poverty, and inequality of health and education unless the particular risks and concerns of those in social housing are addressed. This can only be achieved through investment, integrated service provision that is also more targeted within a system of progressive universalism, and reforms that recognise

the crucial intergenerational continuities of outcomes such as early parenthood, worklessness, ill-health, disengagement and housing need.

Caveats

One important caveat is that the outcomes reported are for families in social housing. We have nothing to say here about the role of social housing for single people, childless couples or the elderly, or about its role for disadvantaged and vulnerable adults. Yet, the relationship between housing provision for these diverse groups may be central to the problems of housing policy. Another important caveat is that the most recent cohort for which child-adult transitions can be observed was born in 1970. These children grew up during a period of large-scale manual job losses and high unemployment. Until the children in the millennium cohort grow up, we cannot observe whether living in social housing (and on a social housing estate) will confer the same disadvantages in a period of high employment.

Housing policy

These findings provide an important underpinning for thinking about contemporary social housing policy.

In the first instance, they underline the findings of previous studies that demonstrate that living in social housing in childhood in the later cohorts is associated with a range of unfavourable outcomes in adulthood. Subsidising housing is apparently either insufficient, or wrongly designed to protect against unemployment or labour market disadvantage, lack of qualifications, or mental or physical ill health, or to combat intergenerational multiple disadvantage.

Social housing not only provides stable accommodation to people who would find it difficult to afford a home, or a suitable home, on the open market. It is heavily subsidised to provide a certain amount and quality of housing, and at a price and through mechanisms intended to leave residents with income for other parts of their life.

The original aims of social housing were complex and contested, from preventing street homelessness, the most egregiously unhealthy conditions and overcrowding, to create filtering-up opportunities for working-class residents (Daunton, 1984), but advocates certainly never imagined long-term negative effects, and ambitions have since developed and grown. By providing universal access to a decent home at an affordable price, it is hoped that housing policy should enable many other aspects of individual welfare and social productivity. Indeed, reconnecting housing to other aspects of social policy was one of then Secretary of State for Communities and Local Government Ruth Kelly's aims in commissioning the Hills review.

The findings from the 1946 cohort in this study very clearly demonstrate that there is nothing inherently problematic about state-subsidised rented housing, even when this is a minority

tenure. The problems associated with social housing have arisen as tenure-based polarisation has increased, through the twin processes of rising owner-occupation and the policy-driven shrinkage and residualisation of the social housing sector, in the wider context of rising inequality in income and wealth. As long as renting from the state continues to be positioned as a tenure of least choice, while the majority aspire to own, it is hard to see these trends being reversed.

An important question to consider is how much we can expect housing policy at the micro level (for example, issues of allocation and length of tenure) to contribute to other areas of social policy while this situation persists. At the margins, policies that allow less distinction between tenures, and mobility between tenures over time, could make a difference. An alternative view is that the promotion of owner-occupation and housing-based wealth inevitably create a situation in which state-provided housing will cater for those who are most vulnerable. The consequences are already being felt in the housing sector. Flint (2006) argues that a new emphasis on multi-agency working, community ownership and neighbourhood-level interventions has given an increased role to social housing for managing populations deemed problematic.

One interpretation of our findings is that we should expect less contribution from social housing to other policy areas, and more investment from other areas of social policy to support people in social housing. In this sense, the emphasis in the housing green paper on efforts across government to address the education, health, employment, transport and other needs of, particularly newly forming, communities is welcome. If more social housing is to be built, it is vital that tenants are adequately supported in employment, education and health.

A second way in which this work can inform policy thinking is in the conceptualisation of the relationships between housing and livelihoods. Like other studies, our empirical findings here compare the effects of social housing to those of other tenures, implying in a sense that social housing is homogeneous and monolithic. However, as we demonstrate in our conceptual model, social housing has a variety of characteristics which impact on livelihood through mediating processes at the area and household level (including household dynamics, local labour markets and education systems) and which are susceptible to policy intervention. A vital next step is to go beyond thinking about social housing per se as beneficial or damaging, and to identify what it is about social housing that is – or what kinds of social housing are – associated with positive or negative effects, thus providing a framework for considering policy alternatives.

Table 13, below, sets out some of the policy alternatives for how social housing might be provided in the UK.

Table 13: Alternatives for housing policy

Characteristics	Policy alternatives
Rented, not owned	<ul style="list-style-type: none"> • Mortgage tax relief for low-income homeowners • Shared-ownership or shared-equity schemes • Discounted purchase of state housing
Subsidy linked to home, not individual	<ul style="list-style-type: none"> • Means-tested housing allowances • Tax deductions for private rents
Provided by a non-profit landlord (usually large-scale, usually with clustered provision)	<ul style="list-style-type: none"> • Subsidies to private landlords to provide sub-market rents • Private landlords voluntarily allocate certain properties for sub-market rents • Provision of rent deposits for use in private sector • Fewer large-scale clusters/mixed communities

One alternative to social housing is to encourage even more people into home ownership, or part-ownership. This has been government policy throughout the period of our study, pursued with differing emphasis and with tools ranging from house-building subsidies to mortgage interest tax relief, the right to buy, and low-cost home ownership models. Our data shows diverging trajectories for people who went into home ownership in the 1950s and 1960s compared with those who did not. Given already very high rates of home ownership, high house prices and increasing costs of borrowing, the benefits of home ownership against social housing need to be carefully weighed up.

Another alternative is to decouple subsidies from the physical stock. One obvious drawback of home-based housing subsidies with local allocations and secure tenancies is that tenants may not easily move their home to take up new work. Hills (2007), using evidence from the Survey of English Housing 2006, shows that social tenants move less often than private renters, and also less far than other tenures. However, tenants are more likely to move than owner-occupiers. Given pronounced differences in worklessness between social and private renters, this seems an important issue. On the other hand, the idea that it is characteristics of social housing tenure that are constraining mobility is contested. The most that can be said at this stage is that some people may be constrained in their mobility by tenure, supporting Hills' (2007) proposal of a varied menu of tenures in order to support different individuals' needs at various life stages, rather than any blanket removal of tenure security.

A final policy issue is that of mixed communities: the idea that social housing would be less disadvantageous if not geographically clustered. It may be that the concentration of people with diverse experiences of multiple deprivation compounds difficulties, in which case it makes sense to build new social housing in mixed communities. However, it has not been demonstrated that changing an area from a social housing area to a mixed-income/ mixed-tenure area will remove effects rather than move people on. The real problem is probably the marginalisation and poverty of social housing tenants. It is important to be cautious about what housing policy can achieve.

Table 14, reproduced from Silverman et al (2006), identifies possible ways in which negative area effects might arise in disadvantaged neighbourhoods and how a mixed communities approach might address them.

Many of these remain untested, and some research casts doubt on whether mixed communities can offset neighbourhood effects in the ways assumed. In particular, owner-occupiers and renters and households from different income and class groups tend to occupy different social spheres and not to mix (Atkinson and Kintrea, 2000; Allen et al, 2005; Silverman et al, 2006), suggesting that any potential benefits from extended social networks or peer interactions cannot be assumed.

Cheshire (2007) has recently suggested that enthusiasm for mix neglects the benefits that may arise from "specialised neighbourhoods" where people share the same consumption

needs, interests and lifestyles and where networks with people like themselves are of value. He cites Bayer et al's (2005) work showing the value of networks with similar people for low-skilled workers in urban labour markets. The work of Ros Edwards and colleagues at London South Bank University is also important here, highlighting the particular importance of bonding social capital for vulnerable or semi-vulnerable communities.

Social housing, throughout its history, has mainly been built with the aim of housing families with children. Families have featured prominently in policies to decide who gets priority for available social rented homes. It may be that understanding how the resources, capabilities, needs and values of diverse individuals and households interact to create communities within and across physical space is key to understanding what is meant by a mixed community. There are dangers to a mixed communities policy that micro-manages lives. Again, the community is key.

Table 14: Neighbourhood effects and mixed communities

Assumed area effects of concentrated poverty	Assumed benefits of mixed communities
<p>Arising from lack of resources:</p> <ul style="list-style-type: none"> • absence of private-sector facilities such as shops or banks • high demands on public services, and poor quality • a poor reputation • high crime and antisocial behaviour 	<p>Arising from lack of resources:</p> <ul style="list-style-type: none"> • more money to support facilities • fewer demands on services, particularly schools. More cultural and social capital to shape improved provision • improved reputation • fewer residents with motivation for crime and antisocial behaviour
<p>Arising from limited interaction between social groups:</p> <ul style="list-style-type: none"> • exposure to disaffected peer groups • isolation from job-finding or health-promoting networks for adults 	<p>Arising from greater interaction between social groups:</p> <ul style="list-style-type: none"> • exposure to aspirational peer groups • access to more advantaged and aspirational social networks
